The greatest potential problem with adobe/earthen buildings is their vulnerability to earthquakes when they are in seismically active areas. Improved building techniques and materials, better architecture and roof design, and better building sites may alleviate most or all of the perceived problems. In the past, the same issues raised for fired brick, cut stone, concrete block, and concrete buildings were resolved. Solving most of the seismic-related concerns with earth and stone construction could have a big impact in alleviating massive death and destruction in cities heavily dependent on earthen construction, including those in developing countries such as Chile, China, Iran, Nepal, and Peru.

Adobe buildings in the United States are commonly constructed on concrete slab foundations and have one or two stories. Designing the slab to resist cracking both during normal life of the structure and possible earthquakes is prudent in seismic areas. Work in California suggests that a combination of techniques can serve to reduce hazards related to earthquakes—proper slab construction; walls reinforced with rebar; wire mesh beneath the plaster and stucco both inside and outside the building; interconnected bond beams and roof beams at the top of walls; and buttresses (Tibbets 1986).

Radon

The identification of radon gas as a health hazard has caused owners to be concerned about the safety of their adobe structures. Radon is a colorless, odorless, heavier-than-air radioactive gas derived from the breakdown of radioactive elements in soil and rock in some parts of the world. The most stable radon isotope, ^{222}Rn , has a half-life of 3.8 days (Wilkening 1980). Radon enters buildings through cracks and accumulates in low spots such as cellars, crawl spaces, and poorly ventilated zones, particularly when they are closed and have a negative air pressure, as is common during the winter months. This problem is not unique to adobe-type structures but commonly occurs in soils overlying granite, black shale, light-colored volcanic rock, sedimentary rock with phosphate, and similar geologic settings. Although adobe buildings have not been shown to have significantly more radon than other types of construction, good ventilation and positive interior air pressure are the easiest ways to alleviate a buildup of radon. Modest changes in construction and care commonly will prevent problems in all but the most severe cases (Smith and Austin 1989, 1996).

Building Codes

The building code for earthen construction in the United States focuses on safety for the inhabitants. In New Mexico and California, two states with numerous adobe structures and substantial seismic activity, the building code specifically addresses the need for adobe structures to endure considerable movement during seismic events (Smith and Austin 1989, 1996). The New Mexico code forbids the construction of adobe structures exceeding two stories in height, and all load-bearing walls must be topped with a continuous belt course or tie beam. The belt course is commonly reinforced concrete, and a tie beam is solid wood and at least 15.24 cm (6 in.) thick. The California building code requires that walls have internal reinforcement with rebar, as well. Following these codes, adobe structures fare about as well in earthquakes as buildings constructed with more conventional materials.

In summary, although adjustments must be made for such problems as possible damage during earthquakes, insulating properties, and radon gas accumulation, these modifications are neither

costly nor difficult to make. In addition, on a worldwide basis, earthen construction offers the considerable advantage of housing a rapidly expanding population with a maximum amount of local building material and a minimal use of expensive energy resources. Earthen construction is indeed the champion sustainable construction material.

Critical Importance in Middle Eastern Countries

Iran, Iraq, Kuwait, Pakistan, and other countries clustered around the Persian Gulf and Arabian Sea are all heavily oriented toward earthen construction. They are also in a region of intense earthquake activity. These countries have much to gain by adopting new building technology, which will cost residents nothing more than the time for instruction.

Because much of Iraq's residential and other construction consists of earthen construction, ongoing rehabilitation of that country after the second Gulf War could benefit greatly from new construction techniques and architecture. The easy availability and low cost of earthen raw materials could significantly ease the expense and time required to bring the country back to its feet. As pointed out earlier, adobe houses are fairly bulletproof and resistant to shell fragments.

FUTURE TRENDS AND INNOVATIONS

Adobe and other types of earthen construction are gaining respectability worldwide, especially as advances in architecture produce better and more livable designs and structures. In addition, improvements such as electricity, air-conditioning, heating, solar heat, and electronics can make a humble earthen structure comfortable and support a high standard of living. Advanced architectural and structural designs in rammed-earth and cast-earthen construction in Australia, South Africa, and selected Latin American countries will encourage more countries with limited construction material supplies to pursue a greater proportion of earthen building.

In the American Southwest, earthen construction will continue to account for about 5% of new residential building. The Santa Fe style of earthen construction continues to be the most popular and will be the preferred type of construction of both low- and high-income groups. The availability of local materials, and the fact that individuals can build the structures themselves, has appeal for low-income groups. Adobe is a preferred type of construction for the wealthy because a superior home can be constructed that is in vogue and is in harmony with nature.

Aggregates

Daniel R. Hack and Dennis P. Bryan

INTRODUCTION

Construction aggregates are sand and gravel and crushed stone used in various types of construction-related applications. They are a high-volume, low-cost, bulk minable commodity. By volume they are the primary ingredient in portland cement concrete (PCC) and asphalt concrete (AC), often referred to as simply concrete and asphalt, respectively. They are generally crushed and processed to a size and gradation suitable for different specific construction applications.

Aggregates have been used since humans first started constructing buildings, cities, and roadways. In early history most permanent construction included stone, but more than 2,000 years ago the Romans were using a form of lime-concrete incorporating broken stone and sand for many of their buildings. The construction aggregate industry, as we know it today in the United States, developed primarily from the need to improve roads. Boston, Massachusetts, is reported to have had the first paved streets by the mid-17th century. Most roads in the 19th century were unpaved, although some city roads were paved with wood planks, gravel, cobblestone, brick, or crushed stone referred to as macadam. In the early 1800s, the government appropriated money for the first national highway, which eventually extended from the Atlantic seaboard to as far as Illinois and was mostly constructed with broken stone. The railroads then dominated aggregate production in the mid-1800s with their need for railroad ballast (Langer 1997).

By the late 1800s road improvement was finally recognized as important, and the industry as we know it today was born. After the automobile was introduced in the early 20th century and became mass produced (putting a theretofore largely immobile populace on the road), the necessity for road improvements and new construction skyrocketed and has yet to subside. The automobile, along with other industrial advancements, changed the lives of ordinary people and increased their standard of living.

The construction aggregate industry in the United States today is the largest nonfuel mineral industry in the country, producing and consuming approximately 2.6 billion t (2.9 billion st) of mined sand and gravel or crushed stone annually, or approximately 10 t per capita. Every population center in every state, from large cities to small towns, requires construction aggregates for growth, infrastructure maintenance, and literally any type of construction. Aggregate production over the last few years has represented the highest production levels ever recorded in the United States, consistently

increasing over the past decade, reflecting the vitality of the country's economy.

This chapter on aggregate markets and uses briefly acquaints the reader with the aggregate industry; its specifications, marketing, and end uses; how construction aggregates are used in our modern world; and why they are important. It discusses aggregate once it has been processed and stockpiled, usually at the site where it is mined. This chapter does not describe in detail how aggregate occurs from a geologic perspective, how it is evaluated and tested, how it is mined and processed, what is involved in developing and permitting a new resource, and what the major environmental and social impacts are of mining aggregates in the modern world. These issues are covered in detail in the Construction Sand and Gravel and Crushed Stone chapters in this volume.

Aggregates are primarily strong, hard, durable, and so und sand and gravel or stone deposits generally mined near where they are consumed. They are mined locally because they are a high-tonnage, low-cost commodity that cannot economically be hauled for long distances without significantly increasing construction costs. After mining, processing consists of crushing, screening, and washing. Aggregates are used primarily in PCC, in AC, and as base material, but there are numerous other specialty uses as well. Strict specifications govern the finished aggregate product to ensure a long-lasting and quality end product.

Many challenges face the construction aggregate industry because of social, environmental, and economic factors. Competing land uses, environmental regulations, negative attitudes toward mining, and the NIMBY (not in my backyard) syndrome are all adversely affecting the industry. Yet there will be a continuing need for an adequate supply of local aggregate because increased transportation costs can negatively affect reasonable consumer costs. So industry must educate the public on the need for aggregates and the realization of industry's commitment to mine responsibly with an emphasis on adequate reclamation or post-mine land use. Gone are the days of leaving a water-filled, steep-sided open pit as a legacy.

Aggregate Types

"Construction aggregates" can be a broad term, including everything from the highest quality crushed rock or sand and gravel used in high-strength concrete applications to ordinary borrow suitable only as general construction fill. This chapter does not discuss ordinary borrow material, and, for the most part, the discussion is confined to

applications for higher-quality construction aggregates, which are hard, durable, and chemically inert. The primary sources of good-quality construction aggregates are either sand and gravel deposits or quarried and underground bedrock sources.

Sand and Gravel

Sand and gravel deposits are found along rivers and streams and their floodplains, in alluvial fans, in glacial and beach deposits, and as paleosediments. Sand and gravel result from erosion of other rock units and redeposition of clasts of these previous rock units in new environments, primarily by the action of running water but occasionally by glaciers, waves, or mass wasting. Size distribution ranges from enormous boulders to rock flour and reflects the distance the individual grains have traveled and the forces involved in transportation. Deposits rich in sand are the result of lower-energy environments where gravels have previously dropped out and only sand particles can be held in suspension. Deposits typically consist of various rock types, reflecting the varied distribution of the parent geology from which the sand and gravel were derived. Quality of the sand and gravel is likewise determined by the qualities of the original parent rocks, the distance the material has traveled, the dynamics of the depositional environment, subsequent weathering that may have occurred, and the age of the deposit. This is vividly illustrated by the lack of gravel deposits along the U.S. Gulf Coast. Here the flat terrain and the scarcity of nearby hard-rock units to serve as a gravel source combined to create an unfavorable, slow-moving depositional environment without gravels.

For higher-quality construction aggregate uses, sand and gravel deposits must contain individual clasts that are hard, durable, and chemically inert. In addition, the deposit should contain sufficient reserves to sustain a mining operation for a suitable length of time.

Crushed Stone

Crushed stone deposits are found where appropriate bedrock exists. Suitable bedrock can occur in sedimentary, igneous, and metamorphic terrains. The primary sedimentary rock deposits are the carbonates, limestone and dolostone. Igneous rocks include plutonic rocks ranging from granites to gabbros and volcanic rocks ranging from basalts to rhyolites. Metamorphic rocks generally include gneiss, marble, quartzite, and argillite. "Trap rock," a common term in the aggregate industry, refers to dark-colored, fine-grained, igneous rocks ranging from diabase in the eastern portion of the country to Recent basalts in the West. Bedrock occurs where tectonic forces and subsequent erosion have exposed the older, indurated hard-rock units and should be free of deleterious constituents and relatively unweathered. As in sand and gravel, suitable bedrock sources must be hard, durable, chemically suitable, and large enough to sustain an extended mining operation.

Other Materials Used as Aggregate

Slag. Slag is a by-product of the iron and steel refining industry. Approximately 20% of the raw material going into the furnaces to produce iron and steel remains behind as slag. It is composed primarily of alumina silicates and is hard and durable. Slag is sometimes an important local source of aggregate in communities close to iron and steel mills. Total slag used as aggregate is relatively small, being less than 0.5% of total aggregate production.

Lightweight Aggregate. The concrete industry uses both natural lightweight aggregate (i.e., pumice and volcanic cinder) and manufactured lightweight aggregate (i.e., expanded clays and shales, perlite, and vermiculite), primarily in concrete masonry units, to reduce weight of individual units. These aggregates are also used in

structural concrete to reduce weight, especially in high-rise buildings. Perlite and vermiculite are typically used for their insulation properties. For a detailed discussion of lightweight aggregates, refer to the *Lightweight Aggregates* chapter of this volume.

Recycled Materials. Recycling of concrete and asphalt has become more prevalent, reflecting the increasing economic advantage of using these materials. Approximately 15 Mt of concrete and asphalt are recycled yearly in the United States (Bolen 2002; Tepordei 2002). As transportation costs, energy costs, and environmental concerns increase, recycling makes better economic sense.

Concrete from demolition and from general construction debris is often collected, crushed, sized, and processed into aggregate base (AB). It is generally not used as an ingredient in new concrete applications because of quality concerns.

Recycling is sometimes used on asphalt roads: existing worn-out surfaces are ground and reincorporated, at a limited percentage, into new hot-mix asphalt surfaces. These recycled asphalt products are referred to as RAP. Lengthy "trains" can often be seen on road construction projects milling and reincorporating the grindings into an on-the-road mixing plant, where it is blended with new hot-mix material, then relaid as a new asphalt surface. In addition, RAP can be used in AB or as road surfacing on unpaved secondary roads to prevent dust and improve performance.

Recycling is most prominent in the larger metropolitan areas where aggregates command a premium price because of associated transportation costs from distant deposits. Also, waste construction materials require disposal, and often it is more cost-effective to recycle than to pay for transportation to remote landfills, which may charge for disposal. Recycling is entirely an economic decision unless mandated by local or federal regulation on some projects.

Other Materials. Occasionally, other materials have been used in concrete and asphalt products for specialty applications. Shredded rubber tires in asphalt, barite in concrete used in radiation shielding, organic waste and wood chips for lightweight applications, broken glass or cullet in AB, and burned coal cinders in cinder blocks.

Production and Consumption Statistics

Construction aggregates are the largest nonfuel mineral industry in the country. As detailed in the two chapters on construction sand and gravel and crushed stone in the *Commodities* section of this volume, approximately 2.6 billion t (2.9 billion st) of aggregate, consisting of both sand and gravel and crushed stone, were produced in 2003, which equates to approximately 10 st for every person in the United States. On a per-capita basis, consumption and production are the standard gauge of measuring and forecasting aggregate. The U.S. Geological Survey (USGS) indicated that 1,260 companies operating 3,300 active quarries in 49 states produced \$8.6 billion worth of crushed stone in 2003, or 1.49 billion t (Tepordei 2003). And 1.13 billion t of sand and gravel, valued at \$5.8 billion, was produced by an estimated 4,000 companies operating at 6,400 locations in 50 states (Bolen 2003). The USGS conducts annual surveys and compiles statistics on aggregates throughout the country. These results, published yearly, are considered the best available statistical analysis for the aggregate industry in the country and are the source of the statistics presented in this chapter.*

* These estimates are based on voluntary responses from producers. Not all producers respond; therefore certain assumptions and adjustments are made to arrive at the final figures. In addition, crushed stone production includes stone used to manufacture cement and lime, which are also considered to be construction materials but, strictly speaking, are not construction aggregates.

The United States imports small quantities (approximately 18 million t) of construction aggregate, mostly crushed stone, from Canada, Mexico, and the Bahamas. At one time, there were imports from Scotland, but closer sources now predominate. Imports are increasing, however. Although imports are a small portion of total aggregate production, they can be a significant portion of the market in those coastal areas where the imports arrive. Imports make up a significant percentage of total aggregate consumption in some areas of the West, East, and Gulf coasts.

Figure 1 graphs aggregate production since 1900, which reflects the industrialization and increased standard of living enjoyed by the U.S. population. It especially reflects the effects of the nation's transportation system as it went from horse-drawn wagons to "horsepower" when it entered the age of automobiles and airplanes. More than one half the aggregate production in the last century was produced in the past 25 years. The construction of the nation's transportation system consumes a good part of the aggregate resources mined and produced. The figure is broken down by sand and gravel and crushed stone; and, as can be seen in the stacked graph, crushed stone production exceeded sand and gravel starting in 1972. This is attributable to the decline of sand and gravel resources through attrition and the exhaustion of resources, but, more important, to the increased conflict of land uses along flatter, lower-lying lands where sand and gravel naturally occur. These lands, especially near metropolitan areas, are becoming more valuable for other uses besides mining as development encroaches on close, available flat lands. In addition, environmental considerations and social pressures (NIMBY attitudes) are driving resource exploitation farther from the cities and from readily visible flat terrain along major drainages where sand and gravel resources are generally located. Aggregate operations are moving to areas in bedrock where visibility is limited and where impacts to groundwater and the environment are more controllable.

Figure 2 displays how aggregate operations are a high-volume, low-cost commodity, located relatively close to the market. Though this figure was compiled with data from the late 1990s, it well illustrates the point at hand: nearly every county in every state in the union has an aggregate source, either sand and gravel or crushed stone or both, supplying local needs. Aggregates are the only mining commodity nationwide that are readily visible to a large proportion of the population: Commuters within our major metropolitan areas often drive by aggregate operations daily. Aggregate mining operations are, by far, the most visible segment of the mining industry in the country with nearly 10,000 quarries and pits, most concentrated near population centers. Therefore, aggregate mining is the most recognizable form of mining to most of the populace.

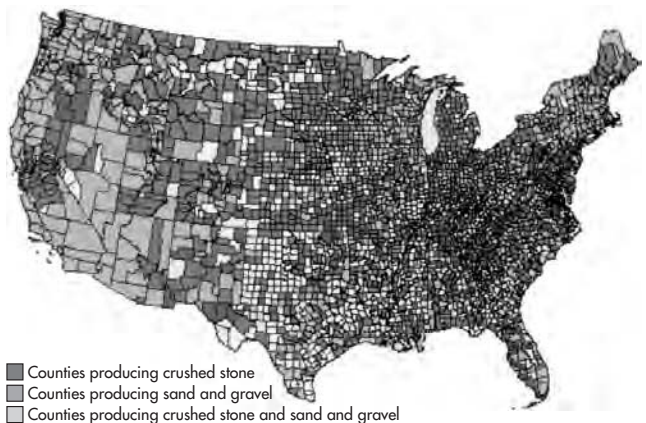

Figure 3 shows the distribution of aggregate production in the United States. It is evident that production mirrors population density. Again, the figure was compiled with data from the late 1990s, but the situation remains the same: The more rural states, most having abundant aggregate reserves, produce only those amounts necessary for consumption in the local area. Another characteristic shown is the production distribution of sand and gravel versus crushed stone. Those states where crushed stone dominates are those where sand and gravel reserves are limited. The eastern portion of the country reflects the increased trend toward crushed stone, and, as can be seen, the majority of aggregate production is in the eastern portion of the country and on the West Coast, where the majority of the population is located.

Table 1 shows aggregate production statistics: tonnages produced, total values, and average unit values. The five leading states for sand and gravel production are California, Texas, Michigan,

Table 2. Aggregate and related construction product price increases, 1994–2003

Commodity	Price Change	Percent Change
Gravel for concrete (f.o.b. plant)	\$9.12–\$10.31	13
Crushed stone (f.o.b. plant) per short ton:		
Aggregate base	\$6.09–\$7.96	31
Concrete aggregate	\$6.77–\$8.27	22
Sand for concrete	\$6.12–\$7.44	22
Ready mix concrete (delivered; standard 3,000-psi mix)	\$50.57–\$76.16	51

Adapted from ENR 1994–2004.

changed relatively little over the past 33 years. As a result of rising costs of labor, energy, and mining and processing equipment, the average unit price of crushed stone, based on USGS statistics, increased from \$1.58/t, free on board (f.o.b.) plant, in 1970 to \$5.78/t in 2003. This, however, parallels or slightly exceeds inflation. Increased productivity achieved through increased use of automation and more efficient equipment was mainly responsible for maintaining the prices at this level. During the 10-year period from 1994 through 2003, the average price of crushed stone for all uses rose from \$5.39 to \$5.78/t, a 7.2% increase. For crushed rock used in concrete, it rose from \$5.58 to \$7.27/t, a 30.3% increase. Prices for sand and gravel during that same period rose from \$4.20 to \$5.14/t for all uses, a 22.4% increase, whereas for concrete sand and gravel, prices rose from \$4.67 to \$5.80/t, a 24.2% increase. *Engineering News Record* (ENR 1994–2004) also tracks published prices for aggregates and related construction products monthly. Table 2, compiled with data from ENR, lists a average price increases for aggregate and related construction products from 1994 to 2003.

These figures for aggregates are averages for the country based on ENR's method of survey (prices in 20 cities throughout the country). Individual commodity prices vary widely from city to city. ENR's typical prices at the end of 2003 for concrete sand ranged from \$4.40 to \$10.95 in the 20-city survey.

In California, the leading producer and consumer of aggregate, the average cost of concrete aggregate was between \$8.00 and \$10.00/st in 2002. In certain large metropolitan areas such as San Francisco, where sand is imported from British Columbia, prices can be as high as \$20/st. This high cost reflects the lack of permitted aggregate resources in the San Francisco Area (Kohler 2002).

The 51% average price increase for ready mix concrete in Table 2 exceeds the aggregate increase. Even though ready mix is approximately 75% aggregate, cement costs over the 10-year period rose more sharply, partially reflecting the higher price for ready mix concrete.

INDUSTRY STRUCTURE

The basic precept of the aggregate industry is making little rocks out of big rocks. The aggregate industry has undergone a dramatic change over the last century. Once confined to small localized deposits, the industry took off with the rise in popularity of the automobile and the government's construction of highways to accommodate those automobiles. By the 1950s hundreds of thousands of roads had been built on the continent, giving birth to the interstate highway system, which had added more limited-access, higher-speed freeways. This increased the trend to larger deposits, bigger companies, and more quarries and pits owned by individual companies. In the 1980s the mergers and buy-ups began. The majority of the "mom-and-pop" operators were bought by larger

Table 3. The 25 leading U.S. companies ranked by total output of aggregates, 2004

Rank	Company	Rank	Company

companies or even international corporations that wanted to broaden their market share and produce additional profits. This trend continues, with major companies expanding throughout the country.

The industry is highly competitive, characterized by thousands of operations selling into regional and local markets. Production costs are mainly determined by the costs of equipment, energy, labor, and compliance with local, state, and federal regulations. These costs vary greatly depending on type and size of deposit, number of products produced, and variability of regulation requirements from state to state and city to city.

Table 3 lists the 25 largest aggregate producers in the country as compiled by the USGS. These companies produce approximately 66% of all aggregate, both sand and gravel and crushed stone, that is used. Many of the companies not only are large by American aggregate industry standards but also are leaders in the mining and processing of aggregate worldwide. Five of the top ten aggregate producers are owned by foreign companies. The combined production of the top ten companies was 43% of the national total for crushed stone as reported for 2002 and 48% for sand and gravel as reported for 2002.

A distinction between sand and gravel and crushed stone producers is not necessarily significant because both commodities are essentially interchangeable when used as construction material, and most if not all the major companies produce both products. The USGS and this volume differentiate the two, however, treating them as separate commodities. They are certainly separate commodities, but the aggregate industry itself seldom differentiates. Both can be used for PCC, AB, and AC as well as other construction applications.

Many companies are vertically integrated, not only mining the raw aggregate material but also using that aggregate in the end product (i.e., concrete, asphalt, and AB). In some instances they are major contractors, specializing in highway and site construction and paving. In this instance they control the aggregate from mining until it is incorporated into finished roadways or associated construction projects.

As companies become larger and more sophisticated in the marketplace, they must become more productive and technical in the modern competitive world. What were once small, local operations now employ more geologists, engineers, and other technical

personnel to run their operation more efficiently. In addition, the structure and corporate cultures of large companies in the aggregate industry have changed over time, reflecting the current social and business environment.

FINISHED PRODUCTS AND SPECIFICATIONS (USES)

Most construction aggregate is used in PCC, AC, and AB. Other specialized uses are railroad ballast, plaster and mortar products, concrete masonry units, filter and drain rock, decorative rock, and others. The aggregate used in these various applications must meet certain specifications because the aggregate influences the physical characteristics of the end product, primarily strength and durability. The aggregate is essentially a filler in PCC and AC applications. Every aggregate deposit must be thoroughly tested to determine if the material meets specifications for these individual products. Often, individual deposits meet some specifications but not others. Aggregate specifications have been developed to ensure the manufacture of durable, strong, chemically resistant end products that can withstand prolonged use and the effects of weathering.

Figure 4a shows end product uses for aggregate derived from sand and gravel, and Figure 4b shows uses for aggregate derived from crushed stone. About half the aggregate (for both crushed stone and sand and gravel) produced in the United States is used in government-funded projects. Of the 1.16 billion t of construction sand and gravel produced in 2003, it is estimated that about 43% was used as concrete aggregates; 21% for road base and coverings and road stabilization; 13% as AC aggregates and other bituminous mixtures; 15% as construction fill; 2% for concrete products such as blocks, bricks, and pipes; 2% for plaster and gunite sands; and the remainder for snow and ice control, railroad ballast, roofing granules, filtration, and other miscellaneous uses (Bolen 2003).

Several entities, both governmental and private, have developed specifications for the various aggregate uses. The American Society for Testing and Materials (ASTM) and the American Association of State Highway and Transportation Officials (AASHTO) are the two most important agencies that developed specifications for all construction materials, including aggregates. ASTM is most commonly used in the private sector, whereas AASHTO is used by the individual state departments of transportation and city and county public works departments. AASHTO aggregate specifications are often

Adapted from Bolen 2003.

Figure 4a. End-product uses for aggregate—construction sand and gravel

Adapted from Tepordei 2003.

Figure 4b. End-product uses for aggregate—crushed stone

adopted from ASTM. Sometimes certain government agencies tighten these specifications even further to improve aggregate performance. For instance, Caltrans (California Department of Transportation) has a more-stringent specification for aggregate used on Interstate 80 over the Sierra crest in northern California. The harsh weather environment coupled with the need for heavy trucks to use tire chains during snowstorms dictated the need for more durable concrete to increase the life of the roadway.

Federal agencies such as the U.S. Bureau of Reclamation, Federal Highway Administration, Federal Aviation Administration, and the U.S. Army Corps of Engineers also have their own specifications for certain construction materials, primarily the end products such as PCC and AC.

In the construction aggregate industry, the definitions of fine and coarse aggregate, whether it is from natural sand and gravel deposits or manufactured from crushed stone sources, can generally be characterized as follows:

- **Fine Aggregate** (natural sand or crushed or manufactured sand)—Granular material passing the 3/8-in. (9.5-mm) sieve, almost entirely passing the No. 4 (0.187-in. [4.75-mm]) sieve, and predominantly retained on the No. 200 (75-μm) sieve (ASTM C125).
- **Coarse Aggregate** (natural gravel or crushed stone)—Granular material predominantly retained on the No. 4 (0.187-in.

[4.75-mm]) sieve (ASTM C125). Construction industry usage commonly restricts gravel size between 1 1/2 in. and 3/8 in. (3.8 mm and 0.95 mm, respectively).

It should also be understood that most oversize material in natural gravel deposits, plus 1 1/2-in. (3.8-mm) material (cobbles and boulders), is crushed to produce both fine and coarse aggregate.

As previously described, construction-fill applications are often cited as a use for construction aggregates, but because fill can be considered ordinary borrow with limited physical requirements, it is not considered here to be a construction aggregate. Construction aggregate implies a unique material that must meet certain physical requirements. Often, ordinary borrow or fill can be satisfied with most any material excavated, whether it be good-quality aggregate or ordinary dirt. Often the overburden and waste from existing aggregate pits and quarries are sold as ordinary fill.

Commodities that use the higher-quality construction aggregates are described in the following subsections.

Portland Cement Concrete Applications

PCC is one of the most common construction products. It is used in virtually every type of construction, from individual homes to high-rise office buildings, from structures along county roads to pavements for multiple freeways, and a part of private, commercial, and public works projects.

Aggregate makes up between 70% and 80% of concrete by volume, or from 75% to 85% by weight. Laypeople often incorrectly use the words *cement* and *concrete* interchangeably. Portland cement is the “glue” that binds the aggregate together to form PCC. The cement is referred to as “portland” because of its unique chemical composition, first developed in England in the late 1890s, in which the resultant concrete had the appearance of a natural limestone near Portland in southern England that was used for building stone. Portland cement is a manufactured product derived from calcining limestone with lesser amounts of alumina, silica, and iron. The resulting clinker is then ground to a fine powder and mixed with a minor amount of gypsum to form portland cement. A detailed discussion of cement is found in the Cement and Cement Raw Materials chapter in this book.

PCC is a mixture of hydrated portland cement, coarse and fine aggregate, water, and air. Hydration of the cement takes place when water is added to the mixture. The water reacts with the cement, hydrating the calcium silicate paste, which quickly solidifies (hardens), binding the aggregate together and forming the finished concrete.

Concrete mixes are variable depending on the application. Strength is determined by the amount of cement in the mix and the water:cement ratio—the lower the ratio, the higher the strength. In general, cement contents in a typical cubic yard of concrete (the general method of measurement) ranges from 4.5 to 7.0 sacks per cubic yard of concrete, which equates to between 423 and 658 lb (192 kg and 298 kg, respectively) of cement per cubic yard of concrete. In addition, a certain optimum amount of water is required for placement to allow the concrete to flow into the forms. Aggregate in the mix must be combined properly to make for a dense mixture where void space is at a minimum and the cement paste fills all the voids. This is accomplished by blending two or more aggregate sizes in predetermined percentages. At least one size of coarse aggregate is blended with a fine aggregate. Admixtures can be incorporated in the mix to reduce water demand, to increase strength, to retard or accelerate setting time, to reduce heat of hydration, to decrease permeability and shrinkage, to make the concrete more durable and frost resistant, and for color. High-strength concretes, >6,000 psi, can be achieved only by using admixtures. A

detailed discussion of PCC concrete is beyond the scope of this article and for further information the reader should contact organizations such as the American Concrete Institute (ACI) and the Portland Cement Association (PCA).

Aggregate properties important to PCC are hardness, durability, soundness, absorption, specific gravity, surface texture, particle shape, cleanliness, size and grading, and chemical inertness. Meininger (1994) gives an excellent discussion of the effect of aggregate properties on concrete.

In general, the most widely accepted specification for concrete aggregates is ASTM C33-03, *Standard Specification for Concrete Aggregates*, summarized in Tables 4 and 5.

Several different types of applications use aggregates in combination with portland cement; these are discussed in the following subsections.

Ready Mix Concrete

Ready mix concrete is batched at a centrally located plant and generally transported by mixer truck fitted with a rotating drum, with internal mixing fins, to a jobsite where it is poured wet into forms. The mixer truck is one of the most recognizable vehicles on our highways. Generally, these trucks carry between 8 and 10 yd³ (6.1 to 7.6 m³) of concrete (up to 20 st). Most concrete is placed in this fashion. Specifications generally require the concrete to be placed within 90 minutes of batching because hydration is progressing. For large jobs, the mixing plant may be located on the jobsite with the plant batching directly in to open trucks that deliver the concrete to the job quickly.

Precast/Prestressed Concrete

Precast concrete is batched and placed into forms in a precast yard making certain structural components, which are better controlled and more economically manufactured at a centralized plant. Examples of precast concrete are pipe, septic tanks, utility vaults, structural concrete beams, and so forth. Generally, precast concrete is structurally reinforced with rebar or post-tensioned or prestressed to impart better tensional or flexural strengths.

Concrete Masonry Units

Concrete masonry units, commonly referred to as block, are a drier concrete consisting of sand, fine coarse aggregate, and water, which are batched, mixed, and then consolidated in molds in block machines. (*Cinder block* is an older term commonly used by laypersons and reflects the fact that cinder was often the aggregate used in block manufacture.) The most standard size block is the 8-8-16 (referring to its dimension in inches) with hollow cores. The masonry units are palletized and delivered to the jobsite on flatbed trucks. They are mortared together in horizontal rows. Masonry units can build structures ranging from ordinary privacy fences separating residential lots to high-rise structural buildings. For structural applications, the hollow cores are then reinforced with rebar and grouted solid with a fine-aggregate concrete mix.

Because masonry units require skilled hand labor for placement, their weight becomes important. A mason can lay more 25-lb (11.3-kg) block in a day than 35-lb (15.9-kg) block. The lightness of the block is therefore a consideration, and often block are manufactured using either natural or manufactured lightweight aggregate. Lightweight aggregates are covered as a separate chapter in this volume.

Mortars, Plasters, and Stucco

Mortars, plasters, and stucco are similar in that they comprise cement and sand mixtures. In addition, they may contain lime,

Table 4. General specification for fine aggregates (natural sand, manufactured sand, or a combination thereof) for use in concrete

Grading	
Sieve Size	Percent Passing
3/8 in. (9.5 mm)	100
0.187 in. (4.75 mm; No. 4)	95–100
0.0937 in. (2.36 mm; No. 8)	80–100
0.0469 in. (1.18 mm; No. 16)	50–85
600 µm (No. 30)	25–60
300 µm (No. 50)	5–30
150 µm (No. 100)	0–10
Limits for Deleterious Substances	
Item	Percent of Total Sample, Maximum
Clay lumps and friable particles	3
Material finer than 75-µm (No. 200) sieve:	
Concrete subject to abrasion	3
All other concrete	5

Adapted from ASTM C33-03.

NOTES:

- The fine aggregate shall have not more than 45% passing any sieve and retained on the next consecutive sieve of those shown in the above table, and its fineness modulus shall not be <2.3 nor >3.1. (Fineness modulus is a factor obtained by adding the total percentages, cumulative, of an aggregate sample retained on each of a specified series of sieves and dividing the sum by 100. The sieves are No. 100, No. 50, No. 30, No. 16, No. 8, No. 4, and 3/8 in. (0.95 mm).
- In the case of manufactured sand, if the material finer than No. 200 sieve consists of the dust of fracture, essentially free of clay or shale, the limits on material finer than No. 200 are permitted to be increased to 5%, for concrete subject to abrasion, and 7% for all other concrete.
- Fine aggregate shall be free of injurious amounts of organic impurities.
- Fine aggregate for use in concrete that will be subject to wetting, extended exposure to humid atmosphere, or contact with moist ground shall not contain any materials that are deleteriously reactive with the alkalis in the cement in an amount sufficient to cause excessive expansion of mortar or concrete, except that if such materials are present in injurious amounts, use of the fine aggregate is permitted with a cement containing less than 0.60% alkalis, or with the addition of a material that has been shown to prevent harmful expansion resulting from the alkali-aggregate reaction.
- Fine aggregates subjected to five cycles of the soundness test (ASTM C88-05) shall have a weighted average loss not greater than 10% when sodium sulfate is used or 15% when magnesium sulfate is used.

which enhances workability. Since they are used in smaller amounts, mortars are usually packaged in bags for easier handling. Mortar is placed by trowel and used to cement block or natural stone together. Plaster and stucco is hand or pneumatically placed onto surfaces for final finishes or to make distinctive textures.

Shotcrete/Gunite

Shotcrete and gunite are specialty concrete products that are pneumatically applied to a surface in contrast to normal concrete, which is placed in forms. Shotcrete, a wet, premixed concrete, is pumped to a nozzle and sprayed. *Gunite* is a trade name for a dry-gunned concrete where the water is added at the nozzle. Common applications are concrete liners in mines and tunnels, slope stabilization structures, swimming pools, and like applications.

Asphalt Concrete Applications

AC, also referred to as hot-mix asphalt (HMA) and most often as just asphalt, is the most common road pavement in the country. It is a flexible pavement compared to the rigid structure of a PCC pavement. Unlike PCC, AC is used only in pavements on grade (i.e., highways, airports, secondary roads, driveways, parking lots, pond

Table 5. General specification for coarse aggregates (gravel, crushed gravel, crushed stone, air-cooled blast furnace slag, crushed hydraulic-cement concrete, or a combination thereof) for use in concrete

Sieve Size	Grading		
	Percent Passing (most commonly used gradations)		
	1 1/2 in. to 3/4 in. (37.5 to 19.0 mm)	1 in. to No. 4 (25.0 to 4.75 mm)	3/4 in. to No. 4 (19.0 to 4.75 mm)
2 in. (50.0 mm)	100		
1 1/2 in. (37.5 mm)	90–100	100	
1 in. (25.0 mm)	20–55	95–100	100
3/4 in. (19.0 mm)	0–15		90–100
1/2 in. (12.5 mm)		25–60	
3/8 in. (9.5 mm)	0–5		20–55
0.187 in. (4.75 mm; No. 4)		0–10	0–10
0.0937 in. (2.36 mm; No. 8)		0–5	0–5
Limits for Deleterious Substances			
Item	Maximum Allowable for the Following Weathering Regions, %		
	Severe	Moderate	Negligible
Clay lumps and friable particles	3.0	5.0	5.0
Chert	5.0	5.0	
Sum of clay lumps, friable particles, and chert	5.0	7.0	
Material finer than 75- μ m (No. 200) sieve	1.0	1.0	1.0
Coal and lignite	0.5	0.5	0.5
Abrasion (ASTM C131-03)	50	50	50
Magnesium sulfate soundness (ASTM C88-05) or when sodium sulfate is used	18 (12)	18 (12)	

Adapted from ASTM C33-03.

NOTES:

- For the sake of brevity, the deleterious substance limit presented here is for concrete exposed to the weather and subject to frequent wetting such as pavements, bridge decks, driveways and curbs, walks, patios, exposed floors and porches, or waterfront structures. Severe weathering refers to a cold climate where concrete is exposed to deicing chemicals or where concrete may become saturated prior to freezing. Negligible refers to a climate where concrete is rarely exposed to freezing in the presence of moisture.
- Coarse aggregate for use in concrete that will be subject to wetting, extended exposure to humid atmosphere, or contact with moist ground shall not contain any materials that are deleteriously reactive with the alkalis in the cement in an amount sufficient to cause excessive expansion of mortar or concrete, except that if such materials are present in injurious amounts, use of the coarse aggregate is permitted with a cement containing less than 0.60% alkalis, or with the addition of a material that has been shown to prevent harmful expansion resulting from the alkali-aggregate reaction.

* Blanks in this table indicate no specification given for this size range.

liners, paths, floors, etc.). AC pavement is generally less expensive than PCC pavement and provides a smoother, quieter ride. (PCC pavements have a hard, rough surface and closely spaced joints.) AC pavements are sometimes referred to as blacktop, as opposed to the light-colored surface of a PCC pavement.

Aggregate makes up between 75% and 85% of HMA by volume, or 90% to 95% by weight. The glue that holds the aggregate together in HMA is asphalt cement, often referred to as *bitumen* or *oil binder*. This “black sticky stuff” comes from oil refining and is the bottom oil left after the lighter oils are cracked or separated out for use as gasoline and other grades of fuels. AC and aggregate are heated together and mixed in what are referred to as HMA plants, which have large burners as components. AC comes out of the plant hot and, for most applications, must be placed hot to obtain the required compaction, strength, stability, and durability. These properties are also dependent on an optimal oil content that is generally dictated by the gradation, absorption, and particle shape of the aggregate. Most asphalt mixes have oil contents between 3.0% and 7.0%. HMA is placed by paving machines in thin lifts and compacted using a heavy roller to achieve the desired end product. Some mixes are described based on their gradation and their utilization for different applications and are referred to by names such as open-graded, dense-graded, and so forth.

Aggregate properties important to HMA are hardness, durability, soundness, absorption, surface texture, particle shape, clean-

liness, size and grading, and affinity for asphalt (stripping). *The Asphalt Handbook* (Asphalt Institute 2004) contains an excellent discussion on the effect of aggregate properties on asphalt. Of special significance is the difference between concrete and asphalt aggregates is that in asphalt, because it is a flexural pavement, the aggregates must be crushed. Crushing produces angular particles with a rough surface texture that better holds the oil and that allows the particles to interlock with one another, giving the pavement better flexural strength and stability. In addition, absorption characteristics of an aggregate are critical. The higher the absorption, the more oil binder required to make a suitable mix, which adds costs because it increases oil demand.

Other asphalt mixes are thin seals or topcoats of asphalt or emulsion mixed with chips or sand to improve and extend the life of existing road surfaces and to mitigate raveling or surface deterioration of existing pavements.

State departments of transportation generally produce specifications for AC aggregates. Table 6 is a typical asphalt aggregate specification.

Aggregate Base Applications

AB is a crushed and screened end product meeting certain gradation requirements. It is not mixed with a binding agent but rather consists entirely of raw processed aggregate. AB is used under asphalt and concrete pavements and other structures for support and drainage.

Table 6. Typical specification for asphalt concrete aggregate*†‡

Sieve Size	Grading Requirements (Percent Passing)			
	3/8 in. (0.95 mm)	1/2 in. (1.3 mm)	3/4 in. (1.9 mm)	1 in. (2.5 mm)
1.5 in. (38.1 mm)				100
1.0 in. (25.4 mm)			100	90–100
0.75 in. (19.05 mm)		100	90–100	90 maximum
0.50 in. (12.7 mm)	100	90–100	90 maximum	
0.375 in. (9.525 mm)	90–100	90 maximum		
0.187 in. (4.75 mm; No. 4)	90 maximum			
0.0937 in. (2.36 mm; No. 8)	32–67	28–58	23–49	19–45
75 µm (No. 200)	2.0–7.0	2.0–7.0	2.0–7.0	1.0–7.0

* Aggregates for hot mix asphalt shall be manufactured from ledge rock, talus, or gravel.

† Los Angeles Abrasion; 500 revolutions; 30% maximum loss; degradation factor, wearing course, 30 minimum; sand equivalent 45 minimum.

‡ Blanks in this table indicate no specification given for this size range.

NOTES: Specifications for aggregates used in asphalt concrete vary from state to state. Other requirements may also include limits on the following based on anticipated weather conditions and traffic loads, end-product application, material type, and availability of suitable material to make aggregate (taken from typical Nevada and California specifications):

Fractured faces, 25% to 90% minimum

Los Angeles Abrasion, 35% to 50% maximum

Plasticity index, nonplastic to 10 maximum, depending on fines content

Soundness of fine and coarse aggregate, 10% to 18% maximum

Absorption, 4% to 6% maximum

Other requirements may include limits on stripping, durability, specific gravity, organic impurities and liquid limit.

* Aggregate base shall be manufactured from ledge rock, talus, or gravel and be free from organic matter and other deleterious substances and shall be of such nature that it can be compacted readily under watering and rolling to form a firm, stable base.

† Blanks in this table indicate no specification given for this size range.

‡ max = maximum.

§ min = minimum.

AB, and sometimes coarser material, is used on soft, wet, or clayey soils for stabilization and to provide a hard usable surface or for a base for other structures. It is usually a 1-in. or 1 1/2-in. minus crushed product. Crushing produces characteristic interlocking particles that add stability and resistance to deformation. Table 7 provides typical specification for AB. The table highlights the great

ranges in gradation and qualifying test methods between various states and is a compilation of typical AB specifications from four specific states. It should be noted that most state highway departments design aggregate base specifications to fit available materials in their respective states for their particular climatic and physical conditions. These specifications show the great ranges in gradation

and qualifying test methods among various states. For more complete explanations of test methods and for other maximum sizes or classes of aggregate bases, the individual state departments of transportation have jurisdiction.

Other Products

Filter/Drain Rock

Filter rock and drain rock are generally free-draining coarse-particle combinations containing little or no fine material that would inhibit free flow of liquids. They are usually 1½ in. (38 mm) maximum for such applications as septic system leach fields or drainage control around foundations. Sand filters are common in wastewater plants.

Riprap/Armor

Riprap is coarse angular cobbles or boulders used as a slope stabilizer to prevent erosion and for slope stabilization. The large particles are generally a quarried product captured at the gizzly before entering the crusher. The angularity helps the interlocking of particles, adding to the intercollective stability. Boulders are sometimes used along coastal area jetties and as armor to combat wave action.

Decorative Rock

Decorative rock can be either sand or gravel or a crushed, quarried rock. It is used as ground cover and for decorative and architectural applications. Usually, it is coarse aggregate particles measuring from less than an inch to many inches across. Decorative boulders used in landscaping often weigh several tons and demand premium prices.

Deicing Sand

Deicing sand, or antiskid material, is unique to those more-northern or higher-elevation environments where winter snow and freezing temperatures create ice and related safety concerns on pavements and roads. The sand, sometimes mixed with salt or other chemicals to help melt ice, is mechanically spread during or after storms to increase traction. Often this sand is limited in the amount of very fine particles allowed, thereby mitigating later fugitive dust emissions when the pavement dries.

Miscellaneous Minor Products

Minor products sometimes produced by construction aggregate operations are pea gravel, golf course sand, septic system sand, ball-field sand, roofing and flooring materials, and many others.

MARKETING AND DISTRIBUTION

General Marketing Considerations

Aggregates are generally marketed to those who use them in the end product, the concrete and asphalt producers. Often these end-product producers are also the same companies who mine the aggregate, a common occurrence referred to as vertical integration. Little aggregate is marketed directly to individuals.

AB is an exception, because it can be marketed to anyone doing construction work, from large construction companies involved in multimillion-dollar projects to homeowners improving a driveway.

Aggregates are a component of all construction products and the major component of some such as highways. Concrete and asphalt suppliers are often subcontractors and must market their products to prime contractors, often through a bidding process. These suppliers, if they do not have their own aggregate source, generally go for the cheapest aggregate price available in the area. Often the decision on which aggregate to use, assuming it meets all applicable specifications, depends on the transportation costs of obtaining that aggregate.

Aggregates are a low-cost, high-volume commodity and therefore very sensitive to transportation costs. For economic reasons, construction aggregates are generally crushed and processed at the mine site. The price of a construction aggregate at the mine site, without transportation, is referred to as the f.o.b. cost. Waste material such as fines, generated as part of the mining process or the result of processing the material into the finished product, costs money to transport. It is more economical to leave the waste on site and transport only the finished product. The ultimate sale price of aggregate products reflects the transportation costs. A 30-mi (48-km) haul can often double the price of an aggregate product's f.o.b. cost. Location of the aggregate source is therefore very important in ensuring a reasonable price for the material. The cheaper the transportation, the cheaper the end-product concrete and asphalt as well. The trend is for aggregate deposits to move farther from the urban centers where those products are most in demand. This is the major factor in the rising cost of aggregate materials.

There are several scenarios on what happens to the finished product once in the stockpile at the mine site. In many cases, concrete and asphalt plants are also at the same location as the mine and processing plant. The aggregate in these instances goes directly from the stockpiles into the concrete or asphalt batch plants. The fresh asphalt or concrete is then hauled to the local, nearby market. It is important to have the batch plants close to the market for several reasons. First, aggregate can be hauled in larger containers than the end-product concrete or asphalt. The finished products must be delivered in manageable sizes so they can be properly placed. The end products are more valuable than the aggregate on a unit basis. The time involved in delivering the finished product (concrete or asphalt) must be considered. When batched, concrete has a limited time before it begins to hydrate and set. Asphalt must maintain a certain temperature for proper placement. If necessary, the aggregate can be hauled hundreds of miles, but not the batched end product.

When there are no local sources, the aggregate has to be brought in from remote locations. It has to be hauled to the concrete and asphalt plants that are located near the urban market. In these instances, the aggregate can be hauled by truck, rail, barge, or ship, depending on economics.

AB is another matter, however, and because it is an end product in itself and is not time-placement sensitive, it can be used directly from the stockpiles at the mine or processing site and hauled long distances before placement.

Transportation

The United States has an extensive network of federal, state, and local highways and roads, an extensive railroad grid, and both inland and coastal waterways. The choice between these three transport methods involves tradeoffs between capital investment and operating expense, extensive roadway systems versus more limited rail and water transport, and high-volume versus limited tonnage shipments. Aggregate inventory stored in stockpiles becomes expensive, and the amount of land available for that storage may be limited. Conversely, when a customer wants an aggregate product, it usually requires timely delivery.

The basic modes of transporting aggregate are described in the following subsections.

Truck

Hauling aggregate by truck is usually the preferred, most flexible, and only method in most locations where the aggregate deposits are within 30 to 50 mi (48 to 80 km) of the market. The advantage of using trucks is that they can go almost anywhere where there is a

road. The disadvantage of truck transport is the cost over longer distances. Obviously, the haul costs per ton go down as the volume of material in a given load goes up. Most truck haulage is by tractor-trailer rig ("eighteen-wheelers"). Most states regulate the trucking industry to a large extent, limiting the allowable loads for a given size and weight vehicle or number of axles. In most states, this limits the trucks to a maximum of 20 to 25 st per load which is, generally, a single or double trailer. In some of the less populous states triple trailers are allowed; these can haul approximately 38 to 40 st per load.

During 2003, approximately 78% of aggregate produced was transported by truck (Bolen 2003; Tepordei 2003). Trucks can usually easily access the finished product within aggregate operations and be loaded using various techniques. They can then deliver their payload via existing roads and can empty their loads relatively easily without specialized equipment. Trucking usually can adjust the timing of delivery to meet customers' needs. Trucking generally requires less initial capital outlay than fixed systems but commonly incurs higher operating costs.

Freight rates for trucks are variable depending on the location, the time it takes to deliver the product, and the size of the truck. In rural areas, and on freeways where a higher speed can be maintained, freight rates can range between \$0.08 and \$0.15 per short ton-mile. In urban areas where traffic is slow and congested, it can be as high as \$0.20 per short ton-mile. Price often reflects the cost of living in certain metropolitan areas.

Rail

Rail transport is important in some of the more urbanized areas of the country where the distances from the aggregate source to the metropolitan areas are more than approximately 50 mi (80 km). Individual rail cars haul approximately 100 to 112 st. Unit trains consisting of 50 to 100 cars can deliver up to 10,000 st of aggregate at one time. Rail rates are less costly than truck rates over long distances; there are, however, disadvantages as well.

The United States has about 149,000 mi (240,000 km) of main-line railroad routes, and during 2003, approximately 2.6% of aggregate production was transported by rail (Bolen 2003; Tepordei 2003). This is a fixed-route system that required considerable capital investment. Rail transport is economical when moving large volumes of aggregate distances not economical for trucks. In rail transport, however, there must be access to the plant, a means to load and unload the rail cars at their destination, and, if the aggregate is not used at their destination, a means for further distribution. Rail access to an aggregate operation potentially expands that aggregate's market area. The distribution of rail lines, however, is far more limited than roads. Railroad schedules and extraneous conditions such as elevation climb, scheduling, and track usage volume also help determine whether rail is the preferred transport method or not.

Rail rates can range between \$0.02 to more than \$0.05 per short ton-mile, depending on the above-outlined conditions and circumstances.

Water

The United States has about 41,000 km of navigable inland channels, exclusive of the Great Lakes. In 2003, about 4.0% of aggregate production was transported by barge (Bolen 2003; Tepordei 2003). Like railroads, this is also a fixed-route system that requires a substantial capital investment in ships or barges and also requires loading and off-loading facilities and equipment. Water transport can be the most economical way to ship aggregate on a per-tonnage basis if the market demands the material and if other sources and methods of transport are not available.

Barges are used for long-distance haulage, i.e., distances generally greater than 100 mi (160 km). Barges and ships are used along both coasts, in the Great Lakes, and along interior navigable waterways such as the Ohio and Mississippi rivers and their tributaries. Inland barges ply the interior rivers of the country and carry aggregate from sources located along rivers in rural areas and to urban areas also located along the rivers. These barges commonly hold 1,500 st and can be grouped into tows of 30 to 40 barges, depending on the width and depth of the waterway and the size of the towboat. Larger oceangoing barges can haul along the coasts. The disadvantages of using barges are that they are limited to navigable waterways and loading and unloading is much more time-consuming than with trucking.

Ship transport is primarily along the East and West coasts, where transporting material hundreds of miles is the norm, primarily from sources outside the United States. On the West Coast, aggregate is shipped in from British Columbia. These ships are 60,000- to 70,000-st self-unloading ships and are relatively new to hauling aggregates. They have a series of bins and belts that can readily unload their aggregate cargo without using shore-based equipment. On the East Coast, aggregate comes in on similar ships from Nova Scotia, and in the Gulf of Mexico region they come from the Yucatan Peninsula. These self-unloading ships are approximately half the price of a barge on a per-short-ton-mile basis.

Imports

The imports briefly mentioned under ship transport are driven by economics, the cheapest aggregate based on the cheapest transportation. For instance, aggregate coming into the San Francisco area from British Columbia travels approximately 1,000 mi (1,609 km) in 70,000-st ships. This material is more economical to use than California aggregate mined in the Sacramento area, which is less than 100 mi (160 km) away. The Seattle, San Francisco Bay, and Los Angeles areas along the West Coast are seeing increased imports from British Columbia and Mexico as locally permitted aggregate resources are exhausted and not replaced. At one time, aggregate came from Scotland by ship to select East and Gulf Coast cities; this has been supplanted by exports from both Nova Scotia and Yucatan.

GOVERNMENT, ENVIRONMENTAL, AND HEALTH CONSIDERATIONS

Mining, including aggregates, is facing many challenges. Issues involving the finished product are noise and dust from trucks and plants, crystalline silica in the aggregate, truck traffic leading to increased congestion and safety issues, and others. Permitting of plants and industrial zoning are as contentious as permitting a new mining operation. Reclamation plans may be applicable to the PCC and AC plants that are part of the mining operation.

The aggregate industry is a highly regulated industry. At the mine, health and safety is regulated by the Federal Mine Safety and Health Act of 1977 and policed by the Mine Safety and Health Administration (MSHA). Section 30 of the Code of Federal Regulations (30 CFR) contains the rules under which the mine operates. At the batch plant, the industry is regulated by the Occupational Safety and Health Administration (OSHA).

A more in-depth discussion of government, environmental, and health considerations for aggregate mining operations under the Construction Sand and Gravel and Crushed Stone chapters in this volume.

INDUSTRY TRENDS AND OPPORTUNITIES

Aggregate resources in the United States are inexhaustible from a purely geological standpoint, and despite environmental, zoning,

and regulatory restrictions no shortages on a large scale are expected in the future. Certain markets will have to import materials, however, and others will find many limitations on mining. The National Stone, Sand & Gravel Association (NSSGA), in their announcement for issues to be discussed at their 2004 Annual Convention (NSSGA 2004), indicated that the state of the American aggregate industry at the dawn of the 21st century is faced with the following challenges:

- Complying with the ever-changing rules and regulations of 10 federal agencies and their state counterparts, plus dealing with local governments and their zoning and permitting processes
- Battling antigrowth, anticonstruction factions who enjoy the benefits of aggregates but do not approve of the process necessary to derive them
- Striving to ramp up efforts so that workers have safe and healthful environments in which to do their jobs
- Training the workforce to operate safely and productively
- Facing how the federal and state governments will continue to fund transportation infrastructure projects so critical to commerce, jobs, and everyday life in our country
- Succeeding in business during a time of national economic volatility

As land-use conflicts, NIMBY attitudes, and environmental pressures increase (resulting in the constantly changing regulatory climate), the ability to mine aggregate is becoming more difficult in the United States, and in most of the developed world as well. Competition fuels technological advancements, managerial evolution, and other economical changes to improve productivity. Government and job requirements demand better quality. Local and regional government entities are recognizing the need for available construction aggregate. Combined, these pressures have and are changing the industry. Some of these changes and adjustments are as follows:

- *Crushed-rock sources predominate.* Crushed rock has become the primary source for aggregate since the early 1970s because sand and gravel is generally found in terrain more suitable for other uses (e.g., flat lands for development, scenic river corridors, wildlife habitat protection).
- *Industry is consolidating.* The aggregate industry continues to consolidate. The small operators are being acquired by the larger operators.
- *Operations are farther removed from their markets.* Aggregate deposits move farther from their markets, necessitating transportation cost increases. Existing aggregate resources in urban areas are closing as permitted reserves are depleted and new resources in urban areas are difficult, if not impossible, to zone properly and permit. Robinson (2004), in a recent article on the availability of aggregate, points out that the number of aggregate operations declined since 1975, implying that transportation distances therefore increased.

Those aggregate operations moving farther from their markets also have the following characteristics:

- They are large operations, sometimes referred to as mega-quarries (10 Mstpy). These large operations economize in scale. By increasing production, they serve a larger market, resulting in fewer quarries.
- They are located along major transportation arteries, whether that is freeway, rail, or waterway.
- They limit their visibility. New quarries want to be out of sight as much as possible to limit visual impact to a generally uninformed and unsympathetic public.

- These outlying pits and quarries often have sales yards closer to the market where the aggregate is off-loaded and redistributed as either raw material or final product.
- *Imports are expanding.* Imports from off-shore deposits are likely to continue to expand as land-use conflicts along the coasts intensify. Water transport allows large tonnages to be shipped long distances. It should be realized, however, that land use, social, and environmental issues are not isolated to the United States. Recent environmental and social issues in Mexico curtailed sand imports into the San Diego area, and recent newspaper articles have highlighted some of the negative aspects of coastal aggregate mining in British Columbia that exports material to the United States.
- *Underground operations are more common.* Underground operations in urban areas are becoming more common, especially in the central and eastern portion of the country where there is an abundance of limestone. The USGS reported 83 underground mines in 17 states in 2002, producing 60 Mtpy (Tepordei 2002). The advantages of going underground are becoming more apparent to producers. Problems that are usually ubiquitous to surface mining such as environmental impacts and community negativity are significantly reduced by going underground.
- *Public awareness and outreach are important.* The industry is becoming more aware of the need for public outreach and of informing the general public about what aggregates are and how important they are in the local community. The distinction between operation of a quarry and operation of a ready mix or asphalt plant sometimes does not matter, because often the plants are in the aggregate pits that furnish the raw material. Unlike most mined commodities, aggregate operations tend to be closer to the urban environment and much more visible than most other commodities mined. The denser the population, the more aggregate pits and related plants necessary to provide materials for a growing lifestyle.
- *Specifications are tightening.* Specifications continue to be tightened in the quest for better roads and more durable concrete and asphalt products. Changing technologies are leading to new types of concrete such as roller-compacted concrete (RCC) and "Superpave" designs for asphalt concrete. Most specification trends tend to be for better gradation control and fewer fines.
- *Plant designs are improving.* Production plants are improving by using more efficient equipment, instrumentation, and computerization to better control production and increase automation. Producers are going to larger plants for economy of size. Information technology will lead to remote monitoring and better asset management systems. Additional emphasis is on preventive maintenance, better equipment utilization, and the use of the Internet for sales and purchases.
- *Mining equipment is changing.* Mining equipment is getting larger for economy of size. The mobile equipment trend is toward satellite global positioning systems (GPS) in real time, which would include optimizing production by using earth-moving system capabilities to replace conventional surveying.
- *Mining is changing.* Using 10–20% of the mined material in some aspect of the product is becoming more important for better profits. An increased effort to ward mine design and planning will add to future efficiency, increased reserves, and longer mine life. Improved blasting techniques will increase productivity.

- *Research is ongoing.* Research has intensified how aggregates influence the end products. Using fines, usually considered a waste product, has become a goal.
- *Local, state, and federal governing bodies must be involved in resource identification and zoning.* An other goal is getting local, state, and federal agencies to recognize the necessity of construction aggregate resource availability into the future and, therefore, to recognize the need for setting aside potential resource areas or zoning that recognizes aggregate extraction as an acceptable use. Requiring covenants with future developers in these areas that include recognizing the necessity for and acceptance of future resource development in these zones is important.

California was in the forefront of recognizing the need to plan for future aggregate resource availability. It is the nation's leading producer and consumer of construction aggregates. The California Surface Mining and Reclamation Act of 1975 required the state to classify land based on its known or inferred mineral resource potential. The primary goal of the land classification was to ensure that the mineral resource potential of land is recognized and considered in the land-use planning process. This land classification has been going on for nearly three decades, with more than 30 individual reports throughout the state, usually in urban areas. The result has been positive in many respects but has not led to adequate resources for the future. The California Geological Survey (Kohler 2002) recently published a map and report on the availability of aggregate in California. The main focus was a comparison of projected aggregate demand for the next 50 years with currently permitted aggregate resources. The results of the study indicated that, of an identified 34 aggregate consumption areas in 2001:

- Seven areas have less than 10 years of permitted resources remaining.
- Five areas have less than 25% of permitted resources to meet the 50-year demand.
- Seven areas have 25% to 50% of permitted resources to meet the 50-year demand.

This information was prepared to assist land-use planners and future decision makers.

- *Concrete industry trends are vital.* The ready mix concrete industry is dependent on aggregates because they make up to 85% of the concrete mix. Trends in the concrete industry include higher strengths, different admixtures addressing end properties, and increased automation and computing. Trucks will be GPS guided with more sophisticated computer control and monitored loading to increase quality control. RCC technology changes are leading to more applications.
- *Asphalt industry trends are important.* The asphalt industry is slowly changing to emphasize *Perpetual Pavement*, or longer lasting, more durable pavements. Recent research, referred to as *Superpave* design, is modifying aggregate specifications, mainly gradation and lower fines content, to improve the life of pavements.
- *Creative mining techniques are available.* Creative mining techniques can allow mining where otherwise it would not have been permitted. Such techniques include the following:
 - Going underground, as previously discussed, where there is less surface disturbance, visibility, and dust. In some cases, permitting is easier, especially if the end product is to be warehouse space and mining is essentially a waste product of building that space.

- Reclamation enhancements with variable slopes with more natural slope breaks and more natural looking obstructions.
- Using the site for something beneficial at the end of the mine life (i.e., parks, lakes with surrounding residential development, stormwater basins, golf courses, or industrial sites). Never leave a big hole.
- Permitting as part of a development. Partnering with a government or private developer to improve the site for construction.
- *Recycling will increase.* Recycling will continue to increase, not only because of environmental pressures but also because of economic stimulation. In urban areas it makes economic sense to recycle rather than landfill inert construction waste. Recycled, or by-product glass, can be used locally rather than shipping it to a distant glass manufacturer at a high transportation cost. Glass cullet, where available, and other recognized industrial wastes can go into AB without negatively affecting performance (McCoy and Kerwit 1999). Also, shingles and scrap tires can be used as lightweight fill in roads or in hot mixed AC in residential paving.
- *Sustainability must be clearly defined.* Sustainable development is a recent and evolving concept encompassing how society might look at the future, guaranteeing a healthy economy yet preserving quality of life, respecting the ecosystem, and recognizing the Earth's environmental limits. Its main premise is that today's actions, although providing for our own future, must not diminish the assets, resources, and capabilities available to our descendants. With reference to aggregates, and other types of mining for that matter, defining sustainability is elusive. Surely recycling and mine reclamation are a part of sustainability, but the development of new resources bends the paradigm. Certainly there would be a threat to the economy if mining were to cease, yet some say there is a threat to the environment if it does not cease. Continued and new resources will be needed if our standard of living is to remain high and continue to improve. Because sustainability implies preserving our way of life and the environment, true sustainability could mean that aggregate (recognized as always being a high-volume commodity necessary for daily life) should continue to be developed as close as possible to its end use to mitigate unnecessary fuel consumption, traffic, and highway wear and tear. It also means we should strive to use higher-quality aggregates that will impart longer life to the end products, concrete and asphalt, so their most-efficient-use life can be realized. The country's infrastructure is aging, and there is a question of whether it is being replaced at a satisfactory pace. Infrastructure includes roads, bridges, airports, seaports, waste-disposal facilities, water systems, and so forth. A tremendous amount of aggregate will have to be mined to rebuild these facilities.
- Recycling and the identification of other potential waste products that could be substituted for natural mined aggregates should be considered. Essentially the bottom line is that aggregates and other mined materials will continue to be a necessary part of life on Earth. Sustainability will evolve to recognize this fact and the industry will evolve to mitigate adverse impacts by creative mining techniques, recycling, and substitution of possible other waste products for aggregate usage.
- *Health and safety issues are important.* Crystal line silica is probably the most important health and safety issue that the

aggregate industry will face in the near future. Crystalline silica has been demonstrated to be a carcinogen, yet silica is ubiquitous in the aggregate industry. The effect of future regulations is unknown.

- *The future of aggregate worldwide is strong.* Worldwide demand for construction aggregates is projected to rise nearly 5% annually through 2007 to near 22 billion t, valued at \$128 billion. China, which is already the largest national market, will record some of the strongest increases, with its rising demand for aggregates reaching 6 billion t in 2007, accounting for nearly one quarter the global total.

ADDITIONAL SOURCES OF INFORMATION

Extensive references exist regarding natural aggregate. *The Aggregate Handbook*, published by the National Stone Association (Barksdale 1991), is a comprehensive discussion of the aggregate industry and is generally considered to be the most complete guide available. The NSGA, which resulted from the merger of the National Aggregates Association and the National Stone Association in 2001, is the principal nationwide trade organization representing the construction aggregate industry in the United States. The association's roughly 900 members represent approximately 80% of the sand and gravel and crushed stone producers in the country. The association conducts workshops, training courses, seminars, and meetings for its members on the entire spectrum of the construction aggregate business.

The USGS compiles and annually publishes comprehensive data on production and consumption of construction aggregate in the United States. They differentiate between sand and gravel and crushed stone. USGS annual publications include *Mineral Industry Surveys*, *Commodity Summaries*, and the *Minerals Yearbooks*. USGS also created the National Atlas of the United States, which shows, under minerals, the locations and certain information on construction aggregate producers in the country. USGS directories list crushed stone and sand and gravel producers and their rankings nationally. *Natural Aggregates of the Conterminous United States* (Langer 1988) discusses the geologic aspects of aggregate resources. The USGS *Minerals Yearbooks* contain comprehensive statistics about aggregate resource production.

Four comprehensive collections of individual papers offer case histories of global issues related to aggregate resources:

1. *Aggregate Resources—A Global Perspective* (Bobrowsky 1998)
2. *Aggregates—Raw Materials Giant* (Lüttig 1994)
3. *Proceedings from the International Symposium on Aggregates* (International Association of Engineering Geology 1984)
4. *Natural Resources in the Geological Environment* (Kelk 1992)

A study of reports in these volumes not only will provide an understanding of the many different environmental impacts related to aggregate mining, but, because of a nearly 15-year time span, will also give a historical perspective of the issues. *Aggregates* (Smith and Collis 1993, 2001) and the chapter on "Coarse Aggregate" in *Geology of Construction Materials* (Prentice 1990), and *Aggregates* (Primel and Tourenq 2000), describe the industry from the European viewpoint.

The geology of aggregates is also occasionally covered in a variety of journals, including the individual state geological surveys and other nationally recognized journals such as those put out by the Society for Mining, Metallurgy, and Exploration (SME), the Association of Engineering Geologists (AEG), and the Industrial

Minerals Forum (IMF). No journal is dedicated specifically to the geology of aggregates or construction materials.

Trade magazines concerned primarily with the aggregate industry are *Rock Products*; *Pit and Quarry*; *Stone*, *Sand*, and *Gravel Review*; and *Aggregate Manager*.

The International Center for Aggregates Research (ICAR), located at the University of Texas, is known for its research into the properties of aggregates, primarily as they relate to end products. ICAR publishes results of their many research programs.

Most of the more populous states have aggregate associations representing the business concerns of their aggregate industry. Sometimes these associations are also part of a wider group of business interests who use aggregate, such as the road builders and concrete producers.

Each state has a department of transportation that often conducts aggregate and end-product research with regard to specific issues in their individual states.

There are other organizations which publish research on aggregates but who are more focused on the end product such as PCC or A.C. The PCA, the ACI, and the National Ready Mixed Concrete Association stress PCC. The Asphalt Institute and the National Asphalt Pavement Association (NAPA) focus on AC. The ASTM covers many different construction materials, including aggregate.

ACKNOWLEDGMENTS

The authors would like to acknowledge the help of Bill Langer and Val Tepordei from the USGS for their help in supplying information and some of the figures and tables used in this chapter. In addition, the authors would like to thank Robert Ganis and Bill Langer for their critical review of the chapter.

Cement and Cement Raw Materials

John D. Macfadyen

INTRODUCTION

This chapter uses the term *cement* in its historical meaning of gray and white portland cement, a crystalline compound of calcium silicates and other calcium compounds having hydraulic properties. Several other hydraulic cements of similar chemical form exist and are produced in similar manner, but they have limited and specialized markets. Much of this chapter applies to these cements as well, although they are not directly discussed. Portland cement is produced by intergrinding cement clinker and gypsum in an approximate ratio of 95:5. Cement clinker is a fused product consisting of principally dicalcium silicate, tricalcium silicate, tricalcium aluminate, and tetracalcium aluminoferrite formed by high-temperature reaction in a rotary kiln of carefully proportioned and blended ratios of lime, silica, alumina, and iron oxide. The lime fraction is derived from limestone in the calcining phase of production. White clinker is extremely low in iron oxide, which requires purer raw materials. Table 1 summarizes typical percentages of clinker compounds for the most common portland cement, Type I.

MARKET

A few large companies dominate the marketing and production of cement. Widely distributed plants minimize transportation costs to customers. Although the volume of cement to be sold in the marketplace can be considered inelastic in the short run, a company's sales effort makes a difference. In any given market, although cement sold by competitors must meet certain basic specifications to be considered, other factors dominate, including delivered cost, quality, prod-

uct consistency, technical assistance, and sales relationships with the user companies. Sales relationships ensure the cement company of consideration in the first place, they allow the settlement of questions surrounding the sale, and they offer the selling company a last "look" before sales commitments are made. Sales relationships are based on positive past relations, trust, and friendship.

In the long run, several factors drive the consumption of cement in the marketplace, including economic growth, private and governmental capital investment, and population growth. Influencing decision makers by promoting the architectural, economic, and durability advantages of concrete also drives the market, as does financial or other assistance to concrete suppliers.

Cement companies often evaluate sales success as their continued penetration of the local or regional market expressed as market share. Sometimes this devotion to market share evades the real corporate target of profitability.

In the 1960s the federal highway program was a chief reason for cement plant expansion, along with the nation's continued economic and population growth. At the same time, a new trend established distribution terminals to sell cement to greater geographical markets accessible via water transportation or favorable rail rates. This trend increased competition and held down profits. From 1957 to 1969 the inflation-adjusted price of cement declined significantly. In the 1970s, real prices began to increase but profits were diverted to meet new environmental requirements rather than creating greater efficiency and capital. With a surge in building in coastal markets in the late 1970s, imports began to be a factor. When cement companies did not make the investment to increase capacity or import cement to

Table 1. Probable clinker compounds in Type I portland cement

Compound	Abbreviation	Common Abbreviation	Oxide Composition	Stoichiometric Composition	Approximate Content in Type I Portland Cement, %

Adapted from Clausen 1960.

* Commercial cements contain 4%–6% gypsum or anhydrite (for regulation of the "setting time" of the concrete), approximately 0.5% each of alkali oxides (Na₂O and K₂O) and uncombined CaO, plus a few percent impurities, largely MgO.

† This composition of the iron-containing phase is an approximation and may range from (CaO)₂Fe₂O₃ to (CaO)₆(Al₂O₃)₂(Fe₂O₃).

meet construction needs, outside entrepreneurs did. These importers were not needed during the recession of the early 1980s, and when sales went down, prices often went down and several left the market. Soon local cement producers took over most of the import terminals owned by those “outsiders.” In the surge of the late 1980s and through today, most imported cement has been sold by the producing companies and basically used to meet peak demands of the market and allow U.S. producers to maintain higher utilization of production facilities even in low-demand times.

Imports of clinker and finished cement peaked at 29.351 Mt in 1999, and 24.756 Mt of that was finished cement. Although clinker imports dropped in 2001 as new capacity came on stream, finished cement imports remained between 24 and 25 Mt. The drop in clinker imports reflected new capacity of domestic U.S. cement producers. Countries with the greatest exports to the United States in the peak year of 1999 were Canada, Thailand, China, Greece, and Venezuela. In 1999, New Orleans was the largest port of entry for cement and clinker, followed by Houston and Detroit. The United States is not a significant exporter of cement. Over the next few years, as new capacity comes on stream aided by the higher cost of imported cement, imports are expected to be flat or drop slightly, but not because of the increased production capacity. This anomaly is due to the regional nature of the market, the high cost of truck and rail transportation, and imbalance between production capacity and demand in any given market. In 1997, with the Asian financial crisis, imports from Asian sources began to increase dramatically. In 2003, with Asian markets improving and ocean freight rates escalating rapidly, import sources to the U.S. market began to shift to South America and the Mediterranean region as ocean freight rates became a greater cost component. U.S.-levied “dumping duties” curtailed imports from Japan, Mexico, and Venezuela.

Within the United States, California, Texas, and Pennsylvania have the greatest cement grinding capacity, and Texas, California, and Florida are the top consuming states. Compound growth rates for cement consumption between 1971 and 2001 show Nevada to be the greatest growth state at 5.6% per year, followed by Utah at 3.6% and Arizona at 3.3%.

The ready-mixed concrete industry dominates U.S. cement consumption, accounting for nearly 75% of all cement consumed. Concrete products account for another 12% to 13%, followed by direct sales of 6% to 8% to contractors on major projects. Building materials firms, which are the key sellers of sack cement, account for another 3% to 4%. Sales to governments, mining companies, waste handlers, and oil-well cementers normally fall in a range of 1% to 2% of all cement consumed. Types I and II account for 88% to 90% of cement sold with a rising amount of Type V of 5% being sold in the last 3 years as Type V becomes required on many California projects. Blended cements run approximately 1% to 2% of sales in the United States. Table 2 lists the American Society for Testing and Materials (ASTM) and the American Association of State Highway and Transportation Officials (AASHTO) standards for the various types of cement.

Table 3 summarizes production, shipments, and imports from 1991 to 2003. The U.S. Geological Survey (USGS) maintains the monthly shipments and import statistics (arithmetic mean) of the industry and also publishes an annual review. Not all importers report their shipments to customers to the USGS; therefore, the USGS monthly production and shipments reports and the import statistics leave a gap of about 2%.

PRODUCTS AND STANDARDS

Table 2 lists the five types of portland cement and their standards for use in the United States. Although the principal standards are

the ASTM values, portland cement for highway construction is held to the AASHTO standards. Masonry cement and various market-driven specialized forms of masonry cement produced in certain markets are typically not held to any standard specifications. Pozzolanic cements and blended cements also must meet ASTM standards, as must blast furnace slag as a portland cement substitute. Blast furnace slag producers are able to demonstrate good 28-day strengths comparable to portland cement standards in addition to alkali reactivity benefits. Where consumers do not stipulate concrete strength requirements, ready-mix producers sometimes substitute fly ash for some of the portland cement.

RAW MATERIALS

Market competition, ongoing pressure on cement prices, and the resultant lower costs of production have changed the framework for locating new cement plants and the types of raw materials for producing cements at new and existing plants. Although the fundamental chemical constituents to produce portland cement have not changed, the choices of raw materials as sources of these chemical compounds have changed and are expected to continue changing. Abundant limestone and argillaceous reserves exist throughout most of North America and many parts of the world, but accessibility, quality, cost of extraction, and transportation increasingly affect cement production economics and therefore the ability to extract these minerals. The increasing demand by governments to recycle materials and the changed economic structure of recycling are having a major impact on the cement industry. Additionally, the effect of more stringent environmental regulations and market forces on quality of cement, and modern preheater and pre-calciner production processes, have forced changes in what raw materials are required for producing cement clinker and cement. The production of cement, however, is a chemical process requiring an accurate and consistent blend of the four key inorganic oxides and the limitation of several undesirable oxides and elements.

Minerals Required

The fundamental chemical compounds for producing cement clinker—lime (CaO), silica (SiO_2), alumina (Al_2O_3), and iron oxide (Fe_2O_3)—are now joined by the increasing need to reduce undesirable chemical compounds such as sodium oxide (Na_2O), potassium oxide (K_2O), sulfur, chlorine, carbon, and organics. Additionally, the increasing use of additives with cement clinker to produce different types of cement has affected the use of other materials such as fly ash, gypsum, synthetic gypsum, anhydrite, blast furnace and metallurgical slags, silica fume, limestone, volcanic ash, etc. Lime is not found in nature; it is created from calcium carbonate (CaCO_3) in the production process or obtained from recycled materials. The other key chemical compounds are found naturally and are also present in many recycled and waste materials. Table 4 summarizes the raw materials used in the production of cement clinker.

Calcium Carbonate Resources and Mining Practices

Limestone continues to be the principal source of CaCO_3 . A common mineral on the earth's surface, CaCO_3 is principally found in nature as sedimentary deposits of marine origin. It is also found as marble (a metamorphosed form of limestone), chalk, marl, coral, aragonite, oyster and clam shells, travertine, tuff, and some other forms. In the United States, environmental regulations have essentially eliminated the use of aragonite and oyster and clam shells, and travertine and tuff deposits are rare sources of CaCO_3 . Low-grade sources of CaCO_3 such as siliceous feldspars and argillaceous limestone, which are upgraded by flotation, are also rare and not processed by North American plants.

* AASHTO 2004; ASTM 2004. Dashes indicate that no standard applies.

† ASTM specifications state that there are cases where optimum SO₃ for a particular cement exceeds the limit in this specification. Where it has been demonstrated by Method C563 that this condition exists, an additional amount of SO₃ in no case more than 0.5 by weight percent of cement, is permissible, provided that when the cement with the additional calcium sulfate is tested by Method C265, the calcium sulfate in the hydrated mortar at 24 ± ¼ hr expressed as SO₃ does not exceed 0.5 g/L. When the manufacturer supplies cement under this provision, supporting data will be provided, on request, to the purchaser.

‡ Expressing chemical limitations by calculated assumed compounds does not necessarily mean that the oxides are actually or entirely present as such compounds.

§ Does not apply when the sulfate expansion limit under Optional Physical Requirements is specified.

** This limit applies when moderate heat of hydration is required and tests for heat of hydration are not requested.

†† This limit may be specified when the cement is to be used in concrete with aggregates that may be deleteriously reactive. Reference should be made to ASTM Specification C33 for suitable criteria of deleterious reactivity.

‡‡ Compliance with the requirement of this specification does not necessarily ensure that the desired air content will be obtained in concrete.

§§ Either of two alternative fineness methods may be used at the option of the testing laboratory. When the sample fails to meet the requirements of the air permeability test, however, the turbidimeter test shall be used and the requirements for the turbidimetric method shall govern.

*** These values were revised in ASTM specifications because of the change in unit from cm²/g to m²/kg.

††† The purchaser should specify the type of setting time test required. If not specified, the requirements of the Vicat test only shall govern.

†††† The strength at any specified age shall not be less than that attained at any previous test age.

§§§ When the optional heat of hydration or the chemical limit on the sum of the tricalcium silicate and tricalcium aluminate is specified.

**** When the heat of hydration requirements are specified, the sum of the tricalcium silicate and tricalcium aluminate shall not be specified. These strength requirements apply when either heat of hydration requirements or the sum of tricalcium silicate is specified.

††††† When the sulfate expansion is specified, it shall be instead of the limits of C₃A and C₄A_F + 2C₃A listed under Standard Chemical Requirements.

Adapted from USGS Mineral Surveys (to adjust for unreported shipments) and PCA 2000–2002.

* Portland and masonry cement, and cement produced from imported clinker, for the 50 states and Puerto Rico.

† Includes portland cement shipped by domestic producers and distributors.

‡ Includes dinker.

§ Annual prices are based on an average per-ton value of cement sales, f.o.b. plant, reported by producers to the USGS.

In the cement industry, lime stone is a generic term that includes calcium carbonate, magnesium carbonate (MgCO_3), and dolomite ($\text{CaMg}(\text{CO}_3)_2$). The geological definition of limestone is a sedimentary rock mostly containing calcite (CaCO_3). Dolostone is a sedimentary rock mostly consisting of dolomite. Magnesite (MgO), derived in the clinker production process from MgCO_3 , is highly undesirable in the formation of cement clinker compounds. Many limestone deposits are unusable for portland cement clinker because of MgCO_3 content. Normally, the upper limit in the limestone is 3%, although this can be less depending on magnesia content in the other required raw materials. The many classifications of limestone are of little concern to a cement producer because the principal factor in selecting a suitable limestone is the CaCO_3 content and the minimization of the undesirable minerals. The ideal “cement rock”—77% to 78% CaCO_3 , 14% SiO_2 , 2.5% Al_2O_3 , and 1.75% Fe_2O_3 , coupled with <3% MgCO_3 , <0.4% Na_2O , and 0.3% K_2O —is rarely found but highly desirable. Limestone with lower levels of CaCO_3 and higher levels of alkalis and magnesia requires blending with high-grade limestone. Limestone normally has to be blended with argillaceous material to adjust the chemistry of silica, alumina, and iron oxide. Limestone that is high in CaCO_3 presents cost and operating challenges to the cement producer because it requires large quantities of argillaceous minerals such as clay, which are usually more difficult to convey, store, and feed.

Sedimentary limestone deposits, the predominant source of CaCO_3 for cement, are principally extracted by bench mining, in which 150-mm to 300-mm holes are drilled in 3- to 4-m patterns to depths of 10 to 25 m, charged with ammonium nitrate and fuel oil (ANFO) explosive and blasted. Typical drill patterns and blasting techniques will fracture the rock to <300-mm size. The rock is excavated with front-end loaders, often of 10-m³ capacity, and loaded into 70- to 90-t haul trucks and transported to the primary crusher. Marl and chalk deposits are increasingly extracted with modern mining machines because they normally do not require drilling and blasting. The typical modern mining machine includes the excavator, primary crusher, and a feeder that deposits the excavated and

Table 4. Summary of raw material used in the manufacture of portland cement clinker in the United States

Types of Raw Materials	
Sources of calcium carbonate	Limestone, marl, chalk
Sources of argillaceous materials	Clay, shale, sand, iron ore, mill scale, bauxite, diaspore, diatomite, staurolite, loess, silt, sandstone, volcanic ash
Waste material substitutes	Fly ash, bottom ash, foundry sand, metallurgical slags

crushed marl or chalk onto moveable belt conveyors for transport to storage and preblending facilities. A trend in the extraction process is to use in-pit, moveable, impactor-type primary crushers and belt conveyors to transport the rock to a fixed secondary crusher and screening plants, thereby reducing the number of trucks and haulage distance. Load-haul-dump practices with front-end loaders are also employed with these in-pit moveable crushers.

The increased emphasis on chemical uniformity and quality in the subsequent processing of the raw materials into cement clinker has caused the proliferation of various techniques of quality control in extracting the limestone and other raw materials. A common practice is sampling and x-ray fluorescence (XRF) analysis of blast-hole drill cuttings to establish rock grade, quality, and alkali levels. Increasingly, plants are installing online prompt gamma neutron activation analyzers (PGNAAs) immediately after the crushing circuits to analyze the quarry run material and control subsequent blending operations to produce kiln feed. There is also an increasing use of x-ray diffraction (XRD) in quality control of kiln feed and the produced clinker. XRF analysis has been the dominant method for the past 40 years.

Underground mining of limestone deposits is not typical of the cement industry, although in coming years this is expected to increase as economically accessible surface or near-surface sedimentary deposits play out, particularly at established plants constricted by urban encroachment. Currently, one U.S. plant obtains its limestone

from underground operations using the room-and-pillar mining method. Those plants located on navigable waterways may have the option of extracting limestone from surface deposits some distance from the plant and transporting the limestone by barge or ship. Currently one U.S. cement plant obtains its limestone from the Dominican Republic and two others receive limestone from Canada. Several U.S. and Canadian plants receive their limestone and other raw materials by barge or ship from quarries separated from the plant. An increasing number of plants have installed overland belt conveyors to transport limestone to the plant over distances of more than 5 km. In several plants, such as those in Great Britain and Trinidad (but none in the United States), marl or chalk or limestone is ground and slurried and then pumped to the distant plant. Several wet-process plants have been replaced with flash-dryer-equipped, preheater calciner systems that accept the slurried raw material transported by pipeline. This method has allowed extraction of limestone deposits heretofore inaccessible or allowed continuation of production at plants that otherwise would have shut down.

Argillaceous Mineral Resources and Mining Practices

The typical practice is to use clay or shale and sand for the silica and alumina, and a source of iron oxide such as mill scale or iron

ore to adjust the chemistry to the desired composition, in addition to the ash in the coal used to fire the kilns. Other natural sources of silica and alumina, such as loess, silt, sandstone, volcanic ash, diaspore, diatomite, fuller's earth and bauxite, are used based on economics and cement quality. Many plants are using waste or recycled materials for this purpose and sometimes are paid to take this material. Although the industry has used power plant fly ash and bottom ash for decades, alkali levels often limit the use of these materials. The variety of recycled and waste materials containing silica, alumina, and iron oxide precludes a complete listing. The principal factor in the selection of the argillaceous component is economic. Often plants have to invest in additional materials handling, feeding, and proportioning facilities to be able to use waste materials, thus reducing the economic benefits. As a result of the economic pressures on the North American cement industry, many plants are using some waste materials in place of natural minerals. Table 5 summarizes the quantities of raw materials used in the production of cement.

The typical methods of extracting clays, shales, and sand have changed little. These raw materials are typically surface deposits, often overburden of the limestone beds. Clay and shale are normally extracted using front-end loaders and loaded into haul trucks.

In some cases, the deposits are first ripped with large bulldozers. When the raw materials are present as overburden, a common practice is to contract for the removal and stockpiling of the overburden to expose sufficient limestone to run the plant for several months. The clay or shale is then reclaimed as required for the process over ensuing months. Increasingly, older plants must remove larger amounts of overburden to expose the underlying limestone. The clays and shales not used in the process are often reused as fill and reclamation material in mined-out areas of the quarry because plants are required to return the mined-out land to a reusable state.

Because most cement production facilities use the dry process, slurring clay in wash mills at the plant is rarely practiced. More typical is the conventional crushing of the clay or shale in crushers designed for these materials and their characteristics. In some plants the clay is dried in a rotary dryer, a crusher-dryer, or a semi-autogenous mill before mixing it with limestone for further processing.

Waste Materials as Substitutes

Beginning in the early 1980s, environmental regulations and political factors in the United States combined with economics of cement production have created a significant incentive to use wastes containing silica, alumina, and iron oxides as raw materials. Some of these wastes contain minor fuel values, such as carbon in fly ash and coal in tailings, which potentially make them more valuable. Stack emission limits in some cases prevent or limit their use, but many plants now use these wastes. Only those plants permitted to use so-called hazardous wastes can use soils contaminated with organic wastes or other hazardous materials as raw materials and then only as part of the fuel to the kiln. The subject of alternate fuels is discussed in the section on Fuel Firing Systems in this chapter. Substituting waste containing lime, silica, alumina, and iron oxide is a practice that is expected to grow and become prevalent throughout the cement industry as environmental regulations spread and economic factors make such use attractive.

Geology of Calcium Carbonates and Argillaceous Minerals

Calcium carbonate originates from the biological deposition of shells and skeletons of plants and animals to form beds of limestone. Some of the beds or formations within a bed were formed by natural precipitation of calcium carbonate taken into solution by carbon dioxide in water, forming calcium bicarbonate. The precipitation process occurs as a result of evaporation or temperature changes resulting in a saturated solution; this genesis, however, is rare. Most industrial quality limestone is of biological origin. Massive beds of limestone accumulated over the millions of years of geologic time. Much of the North American continent in Paleozoic time was under water, allowing the formation of limestone deposits. Typically, limestone resources in the Midwest and the eastern United States are of Ordovician, Devonian, and Mississippian ages. Westward they are often of the younger Cretaceous age.

Most deposits are relatively unaltered with little faulting and folding except those in the mountainous West and the Appalachians where alteration is typical. Steeply sloping or near-vertical beds with not iceable of faults along faults are the rule in these regions. Along the Andes Mountains in South America, extensive alteration of limestone beds is the rule. The prevalence of volcanic action, often evident in the sulfur content of the limestone and the interbedding of volcanic deposits, limits the economic use of these limestones.

Deposits of the argillaceous minerals are also of sedimentary origin. Shales, mudstones, and sandstones are often interbedded with the limestone. Shales, typically beds of clay altered by pressure, and sandstone, beds of sand often cemented by precipitated

silica or calcium carbonate, were deposited as the vast inland waters and oceans covered the land masses. Clays are typically surface deposits of more recent times; in some cases from receding glaciers that covered much of the northern hemisphere.

PRODUCTION PROCESSES

The production of cement begins at the quarry with chemical assessment of the limestone and sources of argillaceous materials. The mining plan to extract these raw materials in today's plants is carefully designed to meet the chemical quality objectives of the various types of clinker to be produced. The height of benches and the extraction plan of the various beds of limestone are dictated by their chemistry and how best to blend these beds to achieve the chemical targets and maximize recovery of reserves. Subsequent process steps continually focus on chemical uniformity of the raw materials and of the feed to the kiln. Greater emphasis is now placed on quick analysis and frequent sampling of material streams including the practice of automated (robotic) sample preparation.

Fundamental Processing Steps

Modern plants, which are diagrammed in Figures 1 and 2, use the process steps described in the subsections that follow.

Crushing and Screening

Rigid rotor impactor-type crushers are favored in plants that use a vertical roller mill to grind the raw materials. Scalping ahead of the crusher reduces the fines and potential for clogging the crusher. Plants that use ball mills to grind the raw materials favor a hammermill-type secondary crusher. Screening the rock from the secondary crusher is the preferred process, with the oversize conveyed back to the crusher in closed circuit. The practice of using gyratory or jaw crushers at the primary stage has given way to use of impactor crushers for cost reasons. Similarly, the use of cone or roll crushers as secondary crushers and a tertiary crushing stage has disappeared except in unusual conditions.

Preblending

Depending on limestone variability and process considerations, preblending is now a common practice. It takes two basic forms; either (1) the limestone is laid down in longitudinal or circular beds in a chevron pattern and reclaimed by mechanical rakes that cut across the layers to produce a more chemically uniform limestone or (2) the various raw material components are stockpiled and reclaimed with weigh feeders in set proportions and laid down in longitudinal or circular beds in a chevron pattern and reclaimed by mechanical rakes that cut across the layers to produce a reasonably chemically uniform feed to the subsequent milling stage. An increasing number of plants use PGNAAs to adjust these weigh feeders to achieve superior blending and uniformity of mill feed. The method selected is dictated by factors such as the chemical and physical variability of the limestone, the moisture content of the raw materials, the physical characteristics (stickiness, particle size, etc.), the space available, number of raw material components, and capital cost.

Raw Material Storage and Milling

Storing raw materials ahead of the raw mill is usually limited to the preblend piles with minimal bin or silo storage. The capital cost of storing materials in silos is significant, and the pressure to minimize capital cost usually dictates only a few hours of mill feed held in bins. Weigh feeders withdraw raw materials from their respective bins in the desired proportion to achieve the required chemical composition and deposit them on a belt conveyor that

Figure 1. Steps in the manufacture of portland cement by the dry processes using a four-stage preheater

Figure 2. Kiln system with five-stage preheater and calciner

feeds the raw mill. A significant improvement in uniformity of mill feed and subsequent kiln feed is achieved by installing a PGNAA on either the mill feed conveyors or on the mill product stream. Although ball mills are occasionally selected to dry grind the raw materials, the preferred dry-grinding mill in the modern plant is the vertical roller mill. This type mill is superior in drying the raw materials using the hot waste off-gases from the kiln system and requires less power. For high raw material moistures (14% to 18%), the vertical roller mill uses a combination of waste kiln system gases and waste hot air from the clinker cooler to achieve a 0.5% to 1.0% product moisture, which a ball mill is unable to do. As plant capacities have increased, the vertical roller mill and its related structure and foundations have gained a capital cost edge. These mills operate at significant pressure drop, necessitating large drives on the exhaust fan and careful attention to the mill feed airlock. None of the types of airlock is problem free, each having their limitations, compromises, and cost consequences. Product fineness from the raw mill has increased in recent years from the 70% to 75% passing a 200-mesh Tyler screen (74 μm) acceptable 25 years ago to 82% to 86% in new plants. Wet- or semi-wet-process plants continue to use ball mills as the method of grinding the raw materials into a slurry. Either of two methods of classifying the slurry is in use: DSM screens or multiple cyclones. Each of these methods has its limitations, compromises, and consequences. Product fineness for the semi-wet-process applications has increased to the same level as that for dry-grinding systems. Slurry moisture content objectives for the older wet process and the new semi-dry processes have been reduced in continuing efforts to reduce fuel consumption. Filtration to lower water content of slurry either with plate filter presses or belt-type filters is encountered in very few older plants (none in the United States).

Blending and Kiln Feed

Blending systems for dry-process plants continue to evolve. The realization that large (50,000-t capacity) silos with a random multi-

ple withdrawal system are costly and do not provide commensurate improvement in blending has focused attention on smaller silos (5,000- to 10,000-t capacity) with inverted cone and random or sequenced multiple withdrawal systems. The older small-capacity silos agitated by compressed air (2,000 to 2,500 t) are rarely applied in modern plants, although they are still used in older plants. Separate kiln feed silos or bins are typically not applied in new plants or found in older plants. Kiln feed systems have undergone significant changes in recent years. Belt-type weigh feeders, always having problems because of the characteristics of kiln feed, have been replaced with flow meters coupled to weigh bins on load cells or the Pfister feeder. These new methods are totally enclosed and spill free, and provide lower operating cost and improved accuracy and reliability without capital cost penalties. Wet-process blending and kiln feed systems are unchanged with two or more slurry tanks, traveling rakes, and compressed air agitation. The number of slurry basins has been reduced and significant improvement in kiln feed uniformity has been achieved by using PGNAAs on the mill product stream to control weigh feeders. Flow and density meters continue to be used on the kiln feed system; using adjustable-speed drives on the kiln feed pumps, however, is the preferred method of adjusting flow rates in place of orifice-type control valves.

Preheater and Precalciner Systems

New plants typically adopt the newest precalciner preheater system. The preheaters are the classic cyclones but now typically of low-pressure-drop (100-mm WC [water column]) design. If kiln feed moisture is a factor, the preheaters will have three or four stages; otherwise the norm is a five-stage preheater. Few new plants are fitted with six stages because the incremental efficiency does not justify the added capital and operating cost. A number of plants in the United States and Canada installed in the 1970s have only preheaters, and typically four stages. Sixty percent to 70% of the calcining is in the rotary kiln portion of the kiln system, and the balance is in the preheaters or in the duct between the rotary kiln

and the lower stage preheater cyclone (riser duct). In most such systems, 15% to 20% of the fuel is introduced in the riser duct. Kiln manufacturers have achieved considerable development in precalciner technology in recent years. Depending on the raw material characteristics and emissions limits (especially NO_x), two-stage calciners and very tall calciners are used. Gas and kiln feed retention times are greater (8 to 10 sec), and various forms of staged combustion are the norm. The evolution of precalciners in the last 15 years has been significant and calcining rates of 90% to 95% are an accepted norm. The typical fuel consumption rate in these calciners is 55% to 60% of the total kiln system fuel. Combustion air for this fuel (tertiary air) is drawn from the clinker coolers through separate ducts at 70 °C to 80 °C. The term *precalciner* continues to confuse because effectively the industry has introduced a distinct step in the process to calcine the kiln feed before introduction into the rotary kiln. The rotary kiln's sole purpose is to complete the calcining and cause the chemical reaction that forms the clinker compounds. The result is smaller diameter and shorter rotary kilns turning at higher rates (240 revolutions per hour) to achieve any given capacity. A recent development has been the use of two support rotary kilns with these more efficient precalciners. This results in lower kiln shell stresses and, when offset by thicker kiln shells, less ovality and greater refractory life. It is not uncommon for these properly designed two-support rotary kilns to operate for more than 12 months without refractory failure or replacement, a significant productivity improvement. Fuel efficiency improvements have also been achieved, although the gap between normal operating fuel consumption and that demonstrated during initial performance acceptance tests remains. The kiln manufacturers continue to use net fuel calorific values in their performance guarantees, but producers must continue to deal in the real world in which fuel calorific values and pricing are quoted in gross values and the unwary encounter the 4% to 9% cost discrepancy in addition to the difference between performance guarantees and real-world operating fuel consumption.

Semidry Kiln Systems

A development of the last 10 years has been the commercialization of the flash dryer to use preheater gases to dry kiln feed slurry. These systems are applied in special circumstances such as converting wet-process kilns to achieve much higher production rates from an existing kiln and clinker cooler or transporting limestone to the plant as a slurry via overland pipeline. Typically a semidry system will double output and lower fuel consumption by about 15% to 20% of any given wet-process kiln. The preheaters are typically one stage and in some cases two stages. The flash dryer is a tall duct, often 100 m tall, in which preheater gases are fed into the bottom around a single-shaft, rigid-rotor crusher and the kiln feed slurry is injected into the hot gas stream. The mass of gas and kiln feed is drawn up the flash-dryer duct and separated in a cyclone. The kiln feed, now at very low moisture levels, is fed into the preheater cyclone for final drying. The kiln feed drops out from the preheater cyclone into either a calciner or a second-stage preheater cyclone and then the calciner. In these systems, the fuel consumption is greater in the calciner than in a typical dry-process precalciner system. Calcining rates typically are greater than 90% and overall fuel consumption is 35% to 50% greater than a five-stage dry-process precalciner system, but still less than a typical wet-process system. It is interesting to note that the most efficient wet-process systems, such as the Holcim plant in Clarksville, Missouri, have almost the same fuel consumption rate as a semidry system but not the rotary kiln refractory life and productivity.

Wet and Long Dry Kiln Processes

The wet and long dry kiln processes are treated together because they are essentially obsolete. They are diagrammed in Figure 3. A significant number of plants in the United States and Canada continue to operate with these types of kilns, their retirement being delayed by favorable economics of their use of waste fuels, relative newness, competitive location, difficult environmental situation preventing new plants from locating in their market area, or other factors. Fuel efficiencies have not changed in the last 20 years because there has been no significant improvement in chain systems or other means. These kiln systems have benefited from the improvement in kiln feed uniformity achieved by using PGNAAs and from introducing car and truck tires as fuel into the kiln downstream of the chain section (mid-kiln firing).

Clinker Cooling

A significant development of the grate cooler in the last 10 years has been the compact cooler with a deep clinker bed depth (800 mm to 1,000 mm) and reduced undergrate airflow rates (<3 kg of air per kg clinker) at significantly higher pressure (1,000 mm WC). These coolers are normally fitted with seven to nine static rows of grates and cooling air introduced to the fixed and movable grates through chambers, not undergrate compartments. The smaller grate areas and lower airflow rates result in a compromise in clinker temperature. The accepted norm of 80°C 25 years ago has given way to 120° to 125°C performance, a figure common 50 years ago but considered unacceptable in ensuing years. Newer plants are now dealing with the consequent problems in cement temperature and storing hot clinker. A perceived benefit of these modern clinker coolers is reduced exhaust airflow rates and higher tertiary air temperatures to the precalciner.

Fuel Firing Systems

Rotary kilns and precalciners are almost exclusively fired by coal or a combination of coal and petroleum coke. Kiln startup and warming is typically either with natural gas or No. 2 fuel oil. The degree of substitution of coal with petroleum coke is dictated by the ability of the grinding mill to reduce the pet coke to a high fineness (90% to 96% – 200-mesh Tyler, 74 µm) and by sulfur dioxide permit emissions rates, because the sulfur content of petroleum coke is significantly greater (5% to 7%) than typical rates in coal (1% to 3%). Outside the United States and Canada, allowable sulfur dioxide emission rates enable producers to use 100% petroleum coke to fire the rotary kiln when stable operating conditions prevail with the high fineness. The combustion temperatures in the precalciner are relatively low (<1,100°C) compared to the rotary kiln, restricting the use of petroleum coke. Direct grinding and firing of coal and petroleum coke has given way to indirect grinding and firing as a result of the need to fire two separate systems, the rotary kiln and the precalciner. The requirement to reduce NO_x emissions from existing kiln systems has also resulted in direct firing being replaced with semidirect firing and indirect grinding and firing to reduce primary air and allow the use of specially designed burners. A greater variety of coal (and petroleum coke) grinding mills is now found in U.S. and Canadian plants. The vertical roller mill with its high-efficiency internal classifier is increasingly used. Replacing the static classifiers with dynamic classifiers in older ring-roller mills has gained acceptance, particularly with the need to grind petroleum coke and coal to higher fineness. Many preheater kilns are now burning tires, often aided by a small tipping fee. The normal practice is to introduce whole tires into the kiln through airlock ports in the riser duct of preheater kilns or into the

Figure 3. Steps in the manufacture of portland cement by the old processes

back end of precalciner kilns. Tires are introduced into long wet and dry kilns through openings in the shell downstream of the chain systems, a process covered by a mid-kiln firing patent issued to Benoit, Hansen, and Reese (1989). A few plants in produce tire chips; the economics, however, are not as attractive. Tires contain significant levels of sulfur and iron. Sulfur content limits substitution rates to typically $< 20\%$ of total kiln fuel. The iron content results in the need to adjust kiln feed chemistry and adds the complexity of a change in clinker chemistry when tire feed rates change abruptly before kiln feed chemistry can be changed. Using waste fuels is increasing, although using hazardous wastes as a fuel is static because of the high cost of permitting and ongoing permit compliance. Plants are seeking various combustible materials that ordinarily are wastes as substitutes for the normal coal or petroleum coke.

Clinker Storage

Environmental emission restrictions have made storing clinker in enclosed structures the norm. The choice of silos or domed or longitudinal storage buildings is typically dictated by economics. Silos (some as large as 50,000 t) offer 100% reclaim without mechanical reclaimers but typically cost more than US\$15 0/t, including the conveying systems. Domed or longitudinal structures require mechanical reclaimers or clinker must be reclaimed by a combination of gravity to conveyors in tunnels and front-end loaders or bulldozers. The capital cost of these systems ranges from US\$100 to US\$120/t of capacity but results in greater maintenance and higher operating costs. A significant trend in the industry is using pan- or bucket-type conveyors for conveying hot clinker. These units are favored when clinker must be elevated to the top of storage silos or circular or longitudinal storage buildings. Although relatively expensive, the low maintenance cost, reliability, low dust emission rates, and ability to convey red-hot clinker favor their use.

Cement Grinding

The industry continues to use the two-compartment ball mill in closed circuit with the air separator type classifier as the principal means to grind clinker and gypsum into cement. Almost all grinding circuits also use heat exchangers to cool the cement before conveying it to storage. There has been extensive application of the high-efficiency air-swept separator in place of the older-technology air separators. In addition to some cooling of the cement, these systems provide a better particle-size distribution, slight improvement in grinding efficiency, and typically improved cement strengths at a given fineness. The competitive conditions in the cement industry have resulted in marketing cements with much greater 28-day strengths in the last 10 years. To achieve these strengths, tricalcium silicate levels have increased and fineness of grind has increased by about 500 Blaine points.

There is considerable interest in using vertical roller mills rather than ball mills for grinding clinker and gypsum. Although the trend is still not established, one plant came on line in 2002 in the United States with this type of mill, and one new plant is still in the permitting stage plans to install four of these types of mills. There are several applications of this type of mill outside North America. Several plants using ball mills have installed high-pressure roll presses to prefracture the clinker before grinding in the ball mill. This technology, which Germany introduced into North America in the mid-1980s, results in a significant total power reduction and improved productivity of the ball mill circuit. The major drawback to its application is the need to maintain an inventory of "pressed" clinker ahead of the ball mill to not compromise ball mill production, because a change in the ball charge of the first

compartment of the ball mill is required. The preferred method of conveying cement to storage is still the screw-type pump pneumatic conveyor.

Cement Storage and Shipping

Cement shipments vary with the season, declining significantly during cold winter months and for short periods during severe hot spells or hurricane-type storms. Consequently, plants must maintain significant cement storage capacity either at the plant or in combination with distribution terminals and distant grinding plants. Those plants on the Great Lakes must also contend with closure of shipping because of ice, typically from mid-December to March. The typical practice of storing cement in silos has undergone an interesting change. The practice for many years was to carefully balance clinker storage with cement grinding capacity and cement storage. Until the mandated storage of clinker in enclosed structures for environmental reasons, clinker storage was less costly. Providing excess cement grinding capacity was economically sound in conjunction with limited cement silos. The recent trend is installing large dome structures to store greater quantities of cement because the cost is about the same as clinker storage. In new plants, cement grinding capacity is more closely matched to plant capacity. Storage silos are still needed to allow efficient loading of bulk trucks and railcars and to maintain an inventory of low-demand cements such as blended cements (Type IP), high early strength (Type III), and sulfate resistant (Type V). Very few plants operate bagging systems. In some cases, bagging cement has been contracted out; in other cases, bagging has been consolidated at one plant in a region. Southern Florida and southern California produce the highest levels of bagged cement.

Special Plant Processes

The production of cement is predominantly of gray cement using conventional fuels to fire the kilns. Three plants in the United States and one in Canada, however, produce white cement—although imports of white cement have a significant market share. One small plant in Juarez, Mexico, and one in Virginia produce special proprietary cements for the U.S. market. Colored cement is produced for decorative architectural purposes at several plants by carefully mixing dyes with gray or white portland or masonry cement.

Automation and Process Control

Considerable advances have been made in the last few years in automation of process control and in motor control. Distributed control systems (DCSs) typically control modern plants using fiber-optic cables as the data highway. Many older plants have been converted to DCSs but more commonly they are connected to programmable logic control (PLC) systems. Cost considerations and the unavailability of replacement parts have necessitated these conversions. The algorithms for process control have not changed significantly in the last 10 years, but the ability to provide quick response and finite control has improved kiln and mill operations. Additionally, the powerful data gathering and diagnostic capacity built into both the DCSs and the PLC systems has greatly improved the understanding of the processes, and has driven improvements in process control and improved compliance with emission limits. Virtually all plants now have a central control room from which the plant is operated, although a few plants still have two control rooms, one for the mills and one for the kilns and remainder of the plant. Commonly a single operator controls all processes from this room with an array of monitors using a trackball or touch screen for motor start and stop and a keyboard for process set-point adjustments. The large modern plants also have a process engineer at a nearby workstation to provide guidance to the

operator and assistance when operating parameters are exceeded or systems malfunction. Mimic boards have been replaced with graphics on the monitors that offer more information and the flexibility to make changes. The emission data gathered at some plants are now sent electronically to environmental agencies at periodic intervals, a feature unavailable just a few years ago.

CAPITAL COST OF MODERN PROCESS PLANTS

The trend to construct large plants has continued as older plants are shut down. A typical modern plant has a capacity of 1.5 to 2.0 Mtpy, although a few plants have come on stream in the last 10 years with capacities in the 0.65- to 1.0-Mtpy range. These smaller-capacity production lines have replaced older, lower-capacity, less-efficient processes. The capital cost for construction of a modern 1.5- to 2.0-Mtpy plant at the site of an older smaller-capacity plant is US\$125 to US\$175 per annual ton of capacity; and for the 0.65- to 1.0-Mtpy plant, the cost is US\$150 to US\$200 per annual ton.

Construction cost of a "greenfield" plant is very difficult to gauge because of the number of variables and the length of time it takes to permit and construct a new plant. Costs range from US\$200 per annual ton for a supersized plant of more than 3.0 Mtpy to US\$225 per annual ton for one of half that capacity.

PRODUCTION COSTS

Production costs in the industry vary depending on age of the plant, type of process, capacity, and unique features. Cash costs range from US\$27.50/t for a modern large-capacity plant to US\$50/t for older wet-process plants. The elements of cash cost are supervision and labor, purchased raw materials, fuel, power, maintenance and parts, operating consumables, local taxes, and miscellaneous costs. Capital recovery costs for a modern low-cost plant add US\$15/t to cash costs. When corporate overhead and sales costs are added, the industry is left with very narrow margins over recent selling prices.

Production costs can be classified as fixed or variable. Modern plants require significantly fewer people to operate and maintain, so labor and management are essentially fixed costs. Purchased raw materials, fuel, power, maintenance and operating supplies, and miscellaneous costs are essentially variable costs although some have a small fixed-cost element. Local property taxes, insurance, and capital recovery are fixed costs. Most kilns are fired with coal, but petroleum coke is substituted when pricing is favorable. A modern plant of 1.5-Mtpy capacity will typically operate at <0.2 worker-hours per ton of cement, 3.2 MJ of fuel per ton of clinker, and 140 kW-hr of electrical power per ton of cement.

EMISSION STANDARDS

U.S. cement plants must meet restrictive emission standards. Although federal regulations stipulate only a limit for particulates from the kiln and clinker cooler stacks, 0.3 lb/st of kiln feed (0.15 kg/t) and 0.1 lb/st (0.05 kg/t) of kiln feed, the reality is that plants have to meet much more stringent regulations, and these are multilayered and not necessarily codified as a uniform standard. The principal emission limits are set by the requirement to meet National Ambient Air Quality Standards (NAAQS) for particulates, sulfur dioxide, volatile organic compounds (VOCs), and carbon monoxide. Building a new plant or replacing an existing process system requires demonstrating that the plant will not "consume" more than the allowable increment of these pollutants in the area of impact. Additionally, these standards may be trumped by the need to comply with a state implementation plan (SIP) that mandates a lower emission level. Many plants are required to meet NO_x emission limits in order for the state to meet SIP requirements. Additionally, plants are now required to meet best available control

technology standards for certain pollutants such as particulates. The Clean Air Act Amendments of 1990 also imposed on cement plants the need to achieve the emission standards set to be the "Best 12%" of the plants. More recent emission standards require that cement plants meet dioxin and furan limits of 0.2 ng per dry standard cubic meter of stack gas. These multiple layers of regulations and emission limits have made permitting new greenfield plants a costly and time-consuming process. Even obtaining permits for new production systems at existing plants, where there are "offsets" created by the new process emitting fewer pollutants than the existing process, takes considerable time despite typically avoiding the more time-consuming permitting process of demonstrating compliance with Prevention of Significant Deterioration of Ambient Air Quality Standards (PSD Review) and the New Source Performance Standards (NSPS Review).

Table 6 presents the NAAQS that new cement plants must demonstrate they meet. This is a complex process that requires mathematical modeling of the emissions from the various parts of the process. Table 7 presents the emission limits of certain hazardous pollutants that new cement plants must demonstrate they meet.

The cement industry has also had to contend with more restrictive emission limits, especially of NO_x and SO₂ but also VOCs and trace amounts of metals. By definition, cement kilns are also major emitters of carbon dioxide, which is an unregulated gas but is a political issue.

Those plants that burn hazardous wastes as kiln fuel must comply with federal regulations under the Resource Conservation and Recovery Act of 1976 (RCRA). These regulations are in addition to those just discussed. Compliance with RCRA regulations imposes a significant cost, partly offsetting the economic benefits of this cost-saving measure.

The U.S. cement industry has developed interesting emission control techniques to comply with permit requirements. To control SO₂ emissions, lime slurry is added to the spray water in gas cooling towers. Although this technique works better with fabric filter air pollution control systems, it is applied on kilns with electrostatic precipitators. To meet NO_x emission limits, the cement machinery manufacturers developed staged combustion systems in the calciners that reverse the NO_x formed in the rotary kiln. Modern calciner kilns emit <25% of the NO_x of older long dry or wet kilns. Kiln burner manufacturers also developed burners that reduce NO_x by up to 66%. To meet the dioxin-furan emission limits, kiln gases are now cooled to <200°C in gas cooling towers or in specially configured duct systems. Modern compressed air atomizing spray nozzle technology combined with gas cooling towers and duct systems designed using computational fluid dynamics allows gas cooling to 120°C with no consequences such as wetting the dust, a remarkable achievement not possible 10 years ago.

The need for reliability in meeting emission limits from clinker coolers has forced plants to install gas cooling systems ahead of the fabric filters which are the preferred particulate removal devices. Very few plants use electrostatic precipitators or gravel bed filters for this function. The preferred gas cooling system is an air-to-air heat exchanger, although these devices are not without their problems due to abrasion, thermal expansion, and contraction resulting in fugitive emissions.

OUTLOOK, FUTURE TRENDS, AND DEVELOPMENTS IN THE INDUSTRY

The U.S. cement industry continues to install single large-capacity kiln and mill systems, a trend that began 50 years ago. In 1960, a very large kiln was 2,000 tpd of clinker. In 1967, the then-largest kiln in the world—4,000 tpd—was installed in Clarksville, Missouri. By

Table 6. National Ambient Air Quality Standards

Pollutant	Primary Standards	Averaging Times	Secondary Standards
Carbon monoxide	9 ppm (10 mg/m ³)	8 hr*	None
	35 ppm (40 mg/m ³)	1 hr*	None
Lead	1.5 µg/m ³	Quarterly average	Same as primary
Nitrogen dioxide	0.053 ppm (100 µg/m ³)	Annual (arithmetic mean)	Same as primary
Particulate matter (PM ₁₀)	50 µg/m ³	Annual† (arithmetic mean)	Same as primary
	150 µg/m ³	24 hr*	
Particulate matter (PM _{2.5})	15 µg/m ³	Annual‡ (arithmetic mean)	Same as primary
	65 µg/m ³	24 hr§	
Ozone	0.08 ppm	8 hr**	Same as primary
	0.12 ppm	1 hr††	Same as primary
Sulfur oxides	0.03 ppm (78.5 µg/m ³)	Annual (arithmetic mean)	No standard applies
	0.14 ppm (366 µg/m ³)	24 hr*	No standard applies
	No standard applies	3 hr*	0.5 ppm (1,300 µg/m ³)

Source: CFR 2004a.

* Not to be exceeded more than once per year.

† To attain this standard, the expected annual arithmetic mean PM₁₀ concentration at each monitor within an area must not exceed 50 µg/m³.

‡ To attain this standard, the 3-year average of the annual arithmetic mean PM_{2.5} concentrations from single or multiple community-oriented monitors must not exceed 15 µg/m³.

§ To attain this standard, the 3-year average of the 98th percentile of 24-hr concentrations at each population-oriented monitor within an area must not exceed 65 µg/m³.

** To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hr average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.

†† The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is ≤1. The 1-hr NAAQS will no longer apply to an area 1 year after the effective date of the designation of that area for the 8-hr ozone NAAQS. The effective designation date for most areas is June 15, 2004.

Table 7. Emission limits of hazardous pollutants and operating limits

Affected Source	Pollutant or Opacity	Emission and Operating Limit
All kilns and in-line kiln/raw mills at major sources (including alkali bypass)	PM	0.15 kg/Mg of feed (dry basis)
	Opacity	20%
All kilns and in-line kiln/raw mills at major and area sources (including alkali bypass)	Dioxins/furans	0.20 ng TEQ/dscm or 0.40 ng TEQ/dscm when the average of the performance test-run average particulate matter control device (PMCD) inlet temperature is 204°C or less. [Corrected to 7% oxygen]. Operate such that the 3-hr rolling average PMCD inlet temperature established at performance test.
		If activated carbon injection is used: Operate such that the 3-hr rolling average activated carbon injection rate is no less than rate established at performance test. Operate such that either the carrier gas flow rate or carrier gas pressure drop exceeds the value established at performance test. Inject carbon of equivalent specifications to that used at performance test.
New greenfield kilns and in-line kiln/raw mills at major and area sources	THC	50 ppmvd, as propane, corrected to 7% oxygen
All clinker coolers at major sources	PM	0.050 kg/Mg of feed (dry basis)
	Opacity	10%
All raw mills and finish mills at major sources	Opacity	10%
New greenfield raw material dryers at major and area sources	THC	50 ppmvd, as propane, corrected to 7% oxygen
All raw material dryers and material handling points at major sources	Opacity	10%

Source: CFR 2004b.

1990, a large kiln in the United States and Canada was considered to be 5,000 tpd, although larger ones were being installed in southeast Asia. Holcim is in the permitting stage of a 12,000-tpd kiln to be installed at a greenfield plant near Bloomsdale, Missouri, on the Mississippi River. Mills have followed a similar trend. Raw materials for a 6,000-tpd kiln system are ground in a single vertical roller mill.

Cement is ground in 6,000-kW ball mills, although typically two mills of this size are required to complement a 6,000-tpd kiln.

This trend to increasingly larger production units is driven by economics. The labor force requirements for a 12,000-tpd plant are 20% greater than those of one half that capacity. The most efficient modern large plants (5,000 to 6,000 tpd of clinker) operate with

100 hourly employees and 30 salaried personnel. The number of items of equipment dictates maintenance personnel requirements. The number of operating personnel is essentially static because of the modern central control systems, the computer controlled process, and the stability of preheater precalciner kilns. Quarrying operations require no more personnel because of the very large sizes of haulage and loading equipment, use of in-pit crushers, and belt conveyor transport systems.

Perhaps the future trend in the industry is described not in terms of major developments but in terms of continued development of large kiln and mill systems and more efficient grinding systems. The 10,000–12,000 kW ball mills are on the way. Vertical roller mills of 12,000 kW are also just a matter of time.

Considerable improvements in automation of process control have evolved over the past 15 years using the modern powerful PCs in tandem with PLCs for motor control and rapid data gathering. A modern plant uses a fiber-optic data highway for rapid data transmission which, with DCS and “smart PLCs,” maintains far more accurate control of the process. This trend is bound to continue as improvements in PCs and PLCs and the process control software continue.

Continued development of emission control systems, principally for SO₂ and NO_x reduction, can also be predicted. Some producers have declared the intention to reduce carbon dioxide emissions from kiln systems. To meet this objective, greater use of pozzolanic materials, both natural and synthetic, is likely. Alternative sources of calcium oxide are also objectives, reducing the amount of limestone required.

There has been considerable consolidation in ownership and number of plants in the last few years. This trend is likely to continue as company managements see the need to lower operating and administrative costs and build fewer, larger-capacity plants. Older wet- and dry-process plants will continue to be replaced with larger plants. The North American cement industry is dominated by major multinationals. About 62% of the production capacity is concentrated in six major international cement companies—Holcim, Lafarge, CEMEX, Italcementi, Buzzi Unicem, and Heidelberg Cement. All foreign companies combined control 80% of the clinker capacity and a greater percentage of cement sales.

ACKNOWLEDGMENTS

The author thanks John A. Ames and William E. Cutcliffe, authors of this chapter in the 5th edition of *Industrial Minerals and Rocks*, who set a standard to be followed with their thorough and well-developed work. The author acknowledges use of Table 2 from their work, updated with a recent change in standards. The author thanks John Rohrer for his contribution to the section on Markets, Eric Hansen for his guidance on environmental standards, F. MacGregor Miller for his guidance on quality control, and Polina Levin for her work on the figures and tables.

ADDITIONAL RESOURCES

A significant body of literature and information on portland cement and its producers exists, not only in the United States but also around the world. Numerous government and Portland Cement Association (PCA) publications cover all aspects of the industry and its vital contribution to raising standards of living. This section lists just a few of the publications readers may wish to consult for more details.

Flooring Materials

Robert C. Freas and Chris Lombardo

INTRODUCTION

One of the first things a person sees when entering a building or room is the floor. It makes no difference whether it is a personal residence, an office, a store, or even an airplane hanger—the floor surface makes a statement. Flooring can be both functional and aesthetic, it makes an impression, and it defines the purpose of the space. In the home, the flooring says something about the residents, their interests, and their priorities. In a commercial space, the floor treatment goes a long way in defining the purpose of the business and the space it occupies.

The selection of a floor treatment is based on the number of alternative choices available to the consumer and the interior designer and/or architect, as well as the functional purpose of the floor. Aesthetics will generally have a far greater impact on floor treatment selection in the home or office than will functional performance. Conversely, cost, functionality, and durability will likely have a greater impact on material selection than appearance in hospitals, schools, and other institutional space; government offices; and retail commercial space.

This chapter presents a review of a variety of flooring materials, the dynamics of the U.S. flooring market, and the role of industrial minerals in various flooring options. It also looks at market trends and the impact on industrial minerals specifications and usage. Although the market information focuses on the United States, the technology and mineral usage is similar to comparable flooring production in most global manufacturing enterprises.

MARKET OVERVIEW

Product Choices and Market Segmentation

Within the flooring industry, products are usually defined as (1) carpet and rugs; (2) resilient flooring, which includes both vinyl tile and sheet goods; (3) ceramic tile; (4) wood; (5) laminates; and (6) specialty flooring. Table 1 shows the 5-year history, in sales dollars, for these groups during the period 1999–2003. Table 2 presents a comparison for the same period based on the square footage of product sold.

Soft surface flooring, which is the industry term for carpet and rugs, is the largest segment of the flooring materials market in terms of both sales dollars and square footage covered. When looking at the sales figures, however, it is apparent that market share for this segment has been declining despite real increases in actual annual sales. In fact, over the past 10 years, this segment's share of

Table 1. U.S. floor covering market sales, 5-year history, million \$

Product Sector	1999	2000	2001	2002	2003
Carpet and rugs	12,248	12,911	12,868	13,200	13,230
Hardwood flooring	1,533	1,634	1,731	1,871	1,983
Ceramic tile	2,040	2,190	2,101	2,340	2,540
Vinyl sheet and tile	1,747	1,803	1,776	1,840	1,786
Laminate flooring	632	737	768	910	1,206

Table 2. U.S. floor covering market sales, 5-year history, billion sq ft

Product Sector	1999	2000	2001	2002	2003
Carpet and rugs	17.17	17.92	17.00	17.50	17.38
Hardwood flooring	0.84	0.83	0.83	0.82	0.84
Ceramic tile	2.08	2.28	2.27	2.63	2.88
Vinyl sheet and tile	3.35	3.27	3.76	3.58	3.55
Laminate flooring	0.36	0.46	0.48	0.68	0.94
Other	1.45	1.47	1.48	1.47	1.50
Total	25.25	26.23	25.42	26.68	27.09

Source: Statistical Report '03 (2004).

the total floor covering market dropped from 66.8% in dollars and 71.9% in square footage in 1992 to 63.4% and 67.7%, respectively, in 2003.

Hard surface flooring has gained market share from soft surface, particularly in domestic markets where hardwood, laminates, and ceramic tile continue to make significant gains. Much of this is attributed to baby boomers and empty nesters who control a significant portion of the disposable income in the United States. This group not only prefers alternate materials, but they are also purchasing better quality goods.

Another factor driving the shift in market share is new home construction. Homes are not only increasing in square footage, but areas in which carpet and vinyl once were dominant—living rooms, dining rooms, kitchens, and baths—have seen an increased demand

for hard surface products. Kitchens, bathrooms, and entryways have been a significant factor in the gains made by ceramic tile, and hardwood and laminates are being specified in place of carpet for living rooms, dining rooms, and occasionally bedrooms.

Growth in market share for hardwood and laminates has been spurred by new product offerings designed for a diverse range of applications. These products include specialized milling to facilitate ease of installation, and include both standard board widths and wide planks. Hardwood products are essentially engineered materials that allow for a variety of design and installation options. Long-strip glueless and solid floors, prefinished flooring, and specialty design inlays are common options available to the residential customer. Wood choices range from the standard and ever popular maple, oak, and cherry to a number of exotic woods, and include such diverse materials as cork and bamboo. Engineered wood floors for high traffic and commercial space include products impregnated with acrylic.

Laminate flooring is an engineered and manufactured floor product that is lower in price than standard hardwood flooring. Laminate products have found wider acceptance over the last 3 to 5 years because the product has benefited by an increased array of products, improved product quality and durability, and an expanded distribution network. The product line has also benefited from the increased availability of trained installers familiar with laminate products and innovations such as glueless mechanical locking floor systems.

Ceramic tile also continues to grow in popularity in the United States. The Tile Council of America reports that per capita usage has increased from 5 sq ft per person in the 1980s to approximately 9.0 sq ft per person in 2002. Unfortunately for U.S. manufacturers, in 1985 imports made up 55% of that usage, and today imports account for approximately 77%. Of the 2.88 billion square feet of ceramic tile sold in the United States in 2003, only 662 million square feet were produced domestically.

The number of domestic ceramic tile producers has dropped dramatically as the trend toward a few large companies buying out smaller family-owned factories continues. Many smaller family-owned factories have simply gone out of business because they have been unable to compete with the lower sales prices available from the larger mass producers. Glazed floor tile that sold for \$0.80 per sq ft in 1990 sells for \$0.65 today, despite an increased array of product choices and designs. European trends toward large-format porcelain floor tile have also made their way into the United States. In the late 1980s and early 1990s, 8 × 8-in. glazed floor tile was most popular, followed by 12 × 12-in. glazed tile. Today, most U.S.-manufactured tile has trended toward large-format tile, up to 18 × 18-in. wall tile, while the majority of the 8 × 8-in. tile, along with new creative surface textures, is being imported. Principal tile-exporting countries to the United States are Italy, Spain, and Mexico.

Vinyl flooring, including both tile and sheet, has lost market share to hardwood and laminate, and to a lesser extent to ceramic tile. Manufacturers have been working hard to maintain market share while maintaining a nearly constant price per square foot. New design motifs with tile look-alike patterns and surfaces have been critical to retaining market share. Nevertheless, the sales of vinyl high-end goods have been steadily declining in favor of lower priced vinyl products. Although vinyl once was second only to carpet as a product of choice in remodeling, less than 22% of vinyl sales were to repair and replacement orders in 2003. At the same time, sales of less expensive vinyl products have increased 50% to 70%, depending on geographic location, as durability and price influence commercial and institutional purchase decisions. Schools, hospitals, and retail space have accounted for a large portion of these sales.

Specialty flooring covers a wide array of products, including terrazzo, natural stone, commercial nonskid surfaces, and so forth. This product group has been nearly constant at a 4.4% market share over the past 5 years. Each of the products included in the specialty flooring category are normally chosen for either a specific architectural effect or a specific functional purpose. These products are normally selected for specific projects, and as such are less subject to market swings associated with commodity-oriented alternate materials.

Sales and Distribution

The sales and distribution of flooring materials have undergone significant changes in the past 10 years. These changes have been brought about by consolidation of the manufacturing community within individual market segments, consolidation between segments, and the market influence of large national retail outlets. These retail chains can influence pricing through their volume requirements and the pressure they can exert on the manufacturer. These macro changes have also resulted in substantive changes throughout the rest of the distribution chain, particularly at the locally owned flooring sales centers.

Consolidation has certainly been evident within the carpet industry—Shaw Industries, Mohawk, and the Beau lieu Group, three of the largest U.S. carpet manufacturers—have all grown through acquisition and now dominate carpet manufacturing in North America. This consolidation has afforded these firms cost efficiencies through reduced overhead and the ability to dedicate individual carpet mills to specific brands and/or quality levels of product with fewer changeovers and larger operating runs. In addition, both Shaw and Mohawk have become more independent in their distribution and broader based in their product offerings. Shaw has gone so far as to open its own showrooms and independent sales centers, and both Shaw and Mohawk have broken away from the large industry shows (such as the annual “Surfaces”), and are doing their own trade shows that focus solely on their product lines.

Consolidation has also occurred in ceramic tile manufacturing. Two of the largest U.S. tile producers—Dal-Tile and Florida Tile—have been sold in the last 5 years. This included Mohawk’s acquisition of Dal-Tile to create the largest flooring manufacturing company in the United States. In addition, Marazzi (Italy) and Rocca (Spain) have either acquired U.S. manufacturing capacity or built plants of their own in the United States. As a result, the U.S. ceramic tile industry is, in large part, dominated and controlled by foreign interests.

On the distribution side, Home Depot and its Expo Centers has become the largest outlet for flooring in the United States. The company’s purchasing power has put tremendous pressure on manufacturers to control cost and has had a negative impact on some independent dealers. The outcome has been increased focus by independent carpet and floor retail stores on higher quality goods, custom products, and design assistance. This is particularly true with hardwood and ceramic tile, and the trend has been complemented by the company’s support and training of well-qualified installers. Many of these stores also carry adhesive, grouts, and the requisite installation tools.

Market Segments and Minerals Function

Carpet and Rug

Most wall-to-wall carpet is produced with a three-layer composite backing that includes a primary and secondary backing with an intermediate adhesive latex binder. The primary backing is usually a polypropylene woven fabric into which the carpet yarns are tufted.

The secondary backing, which is in actual contact with the floor surface, is a woven synthetic fabric that is laminated to the back of the carpet with an adhesive binder. The binder will normally consist of styrene butadiene rubber (SBR) latex in residential carpets or polyurethane foam for commercial and heavy-wear carpets.

The binder is the only element in carpet construction that uses mineral materials. Ground calcium carbonate (GCC) with 60% to 70% passing a 200 mesh screen is generally the filler of choice in residential carpet. GCC is used to lower the cost of the binder, and to increase weight and stiffness. Commercial grades of carpet will frequently use alumina trihydrate (ATH) in place of the GCC. ATH is a mineral fire retardant and is used to increase the UL rating of the carpet where more stringent fire regulations may apply.

Resilient Flooring

Resilient floor covering utilizes GCC, and occasionally titanium dioxide (TiO_2) or talc. Some specific product formulations may require minor amounts of kaolin. With few exceptions, the GCC utilized by this industry will have a whiteness and brightness specification with a minimum Hunter L value of 90, and usually higher. Mineral filler has a distinct impact on the color of the vinyl flooring and must have lot-to-lot color consistency and be totally free of dark specks or contaminants. Graphite specks are particularly detrimental as they may contribute to secondary color rings analogous to petroleum products in water. Depending on the desired color of the product, TiO_2 may be used to adjust and/or stabilize the whiteness of the product.

Talc and kaolin are minor fillers in resilient flooring; both are more commonly used in sheet goods than tile. When used, talc is normally used for color adjustment and as a replacement for both GCC and TiO_2 . Kaolin may be used in specific commercial products, particularly where durability and acid resistance are important functional features.

Ceramic Tile

Ceramic tile production can be distinguished by four uniquely different tile categories, as discussed in the sections that follow. Each type has its own specific raw material requirements and significantly different firing characteristics.

Wall tile is a low-temperature, glazed tile with weak fired strength and 15% to 18% water absorption. Formulas usually include talc and/or pyrophyllite and ball clay. This tile is used on walls and occasionally low-traffic and residential floors. Wall tile will not hold up in high-traffic areas.

Ceramic mosaic tile is a porcelain tile no larger than 2×2 in. It is fired to water absorptions of 0.1% or lower, and formulas use feldspar or nepheline syenite for a flux, and ball clay or kaolin for the clay fraction in the body.

Glazed floor tile (Monocottura) is usually 8×8 in. or larger. It is fired to 2% to 3% water absorption. Formula requirements include feldspar or a local flux, and ball clay that is used for the plastic fraction of the tile composition. Body color does not matter because this tile has a 100% glazed surface.

Porcelain (Porcellanato) is a high-temperature floor tile fired to 0.1% water absorption or lower. Its high strength allows it to be used in the most demanding commercial applications. Body color is important because only a portion of the surface is decorated. This tile requires feldspar or nepheline syenite as a flux. Ball clay and kaolin normally are used in the plastic fraction in the body.

Calcium carbonate is used in some, but certainly not all, tile formulations. When used, the carbonate may be present in either the body or the glaze, or in both. In the body, calcium carbonate helps control firing viscosity and reduces the temperature at which

the tile will cure. In the glaze, carbonate tends to reduce the gloss or luster and is used to enhance the color of several pigments such as chromium. Calcium carbonate, however, will increase brittleness and is normally restricted to wall tile.

Specialty Flooring

Terrazzo, nonskid epoxy industrial floor paints, and rubber are three flooring materials that use mineral products. Natural stone is cut or slabbed and is not really manufactured flooring.

Terrazzo is a composite material poured in place or precast. It consists of marble, quartz, glass, or another suitable chip, and is poured with a binder. The terrazzo is cured, ground, and polished to a smooth surface or otherwise textured finished surface. Terrazzo chips may include calcareous serpentine, marble, onyx, and so forth, which take on a polish when ground. Chips of other materials such as granite, quartz, and silica pebbles may be used when the surface does not require a polish.

Nonskid epoxy paints are used in a variety of commercial applications ranging from airplane hangers to warehouse floors. These paints utilize fine sand particles that provide skid resistance without creating such a rough texture that they impede oil and grease spill cleanup.

Rubber flooring may be filled or unfilled. Rubber floor mats, runners, and stair treads may contain GCC to lower cost and impart stiffness. Barytes may also be used to increase weight, and ATH is used to provide fire retardance.

Manufacturing Locations

Of all segments in the category of floor covering materials, carpet and rug manufacturing are by far the most geographically concentrated. More than 75% of manufacturing capacity in this industry is concentrated in northern Georgia, with the majority at Dalton, Georgia. Fifteen years ago, there were carpet mills scattered through Alabama, the Carolinas, Georgia, and Tennessee, but today there are only two major carpet mills in the Carolinas, one in Alabama, and one in Tennessee. Conversely, there are 51 carpet mills and finishing houses in north Georgia that together consume more than 590,000 t of mineral filler annually. There are several small mills scattered about the eastern half of the United States, principally in Pennsylvania and Virginia. The only area of major carpet production outside Georgia is in Southern California, where there are 12 mills using about 90,000 t of mineral filler annually.

Resilient flooring manufacturing plants, unlike carpet plants, are scattered about the United States, located strategically to serve major population centers. There are a dozen plants producing tile or sheet goods in eastern Pennsylvania, New Jersey, and New York. Plants are also located in California (5), northern Ohio (3), and scattered throughout the southwest and south-central states of Oklahoma and Texas. Nevertheless, several plants have closed in the last 3 to 5 years, and this trend is expected to continue as the industry consolidates production to reduce costs.

Ceramic tile is produced in several states but is notably concentrated in the states of Tennessee and Texas, where the plants are relatively close to the sources of one or more raw materials. New plant construction includes the expansion of Crossville Porcelain and the new GrantiFiandre plant, both located in Crossville, Tennessee, and Dal-Tile's new facility in Muskogee, Oklahoma. There are also several large ceramic tile plants in Mexico, although many of the raw materials are sourced in the United States. As noted previously, nearly 78% of the ceramic tile sold in the United States, especially floor tile, is imported, with 35% of these imports coming from Italy, 18% from Spain, 13.5% each from Mexico and Brazil, and the remainder from other countries.

Table 3. Raw material use by flooring industry segment, kt

* NA = not applicable.

Raw Material Requirements

The specifications for individual minerals used in the flooring industry vary greatly, both by end use and by manufacturer. In many instances, the minerals provided are engineered blends that satisfy specific performance parameters required by the manufacturer.

Table 3 provides a general summary of the raw materials consumed by the various industry segments, including tile production in Mexico. It should be noted that the raw materials figures for ceramic tile are very generalized because there are at least four different primary tile types, including variations of each tile group. The same could be said of specialty flooring materials because so many different products and processes are included in the category.

Ball clay producers benefit from the trend toward porcelain tile. The consistent chemistry and processing characteristics of commercially produced ball clay are necessary for porcelain tile, but engineered clay blends designed to meet specific customer formulations must be used. Thus, the technical capabilities and support available from the clay producer has become increasingly critical to sustaining customer relationships.

Feldspar production from North Carolina has increased in volume because of the trend toward porcelain. The combined sodium and potassium content of 10%–15% makes this a good material to flux the body to below the required 0.50% water absorption.

Nepheline syenite from Arkansas currently is being used for glazed floor tile and is being evaluated for porcelain. The higher iron content of the Arkansas nepheline syenite, 3% to 5%, will not produce a white porcelain; however, Canadian nepheline syenite, with lower than 0.3% iron content, is being investigated for white porcelain needs.

Tables 4 and 5 show variations in the raw materials requirements of the different tile species.

SUMMARY AND CONCLUSIONS

A large volume of mineral materials is consumed by the floor covering industry. The changing dynamics of this industry, including major switches between market segments, consolidation among both consumers and producers of mineral products, pricing pressures driven by changes in the distribution chain, and engineering and architectural design trends continue to impose changes on the mix of minerals supplied to flooring manufacturers. Although GCC is expected to continue to dominate mineral use in flooring, specification revisions and increasing functional performance requirements are having an impact on even this mineral staple.

Particle packing, flowability, and controlled particle size distribution are just some of the issues being raised by manufacturers. It is becoming even more critical, then, for the mineral supplier to be able to provide competent technical support to the end user.

Table 4. Raw materials requirements for wall tile formulas

Raw Material	Composition Range, %
Non-talc	
Sodium feldspar	17–14

Feldspar	52	
Kaolin	19	
Silica	5	
Talc	1	
Shrinkage	10	7.5

As demands for mineral performance increase and more rigid specifications are imposed, pressures to eliminate or reduce unit prices for mineral products also increase. The emergence of the “big box” building materials stores and their dominance in the sale of flooring products has placed enormous pressures on flooring manufacturers and consequently on the mineral producer. Unfortunately,

this pressure also has led to a decline in product quality, particularly in imported porcelain floor tile.

Two significant trends dominate the U.S. floor tile industry: the trend toward porcelain tile and the trend toward only large companies being economically competitive. The sale price for ceramic tile continues to drop, which is forcing companies to lower their production costs. In the case of porcelain tile, this has forced producers to push the limits of production specifications as they turn out thinner, lighter weight tile with higher water absorption and reduced strength. This favors large producers who can buy state-of-the-art production facilities and spread their overhead costs over millions of square feet.

Gypsum Plasters and Wallboards

Paul J. Henkels

INTRODUCTION

Gypsum is one of the most widely used and versatile minerals. In the United States, gypsum resources are considered inexhaustible. Most gypsum is used to make wallboard for homes, offices, and commercial buildings; a typical new American home contains more than 7 t of gypsum (Olsen 2001). Moreover, gypsum is used worldwide in cement and concrete manufacture for highways, bridges, buildings, and many other structures that are part of everyday life. Gypsum also is used extensively as a soil conditioner on large tracts of land in suburban areas, as well as in agricultural regions. This chapter focuses mainly on the United States because it has the largest amount of gypsum in the world and because usage statistics are readily available through the U.S. Geological Survey (USGS) and organizations such as the Gypsum Association.

Gypsum has a long history of usefulness to humans. The earliest known use of gypsum plaster dates back some 8,000 years with the discovery of its use in Anatolia. Around 3700 BC, at the time of the pharaohs, Egyptians observed that gypsum rock broke down into a powder when exposed to fire, and that when it was mixed with water, it would form a putty that could be plastered on rough mud brick or stone walls to make a smooth finish. Iranians, Babylonians, Greeks, and Romans were familiar with the art of gypsum plastering as well. Examples of its use include the walls of Jericho, the pyramid of Cheops, the palace of Knossos, and the decorated interior walls of Pompeii.

Although gypsum was used in a limited way for ornamental purposes down through the centuries, gypsum plaster did not achieve wide acceptance because its quick (25 to 30 min) setting, or hardening, time made it difficult to use. The first real understanding of gypsum chemistry was developed in France about 1760 and the gradual growth of its present utilization dates from that time. Craftspeople firmly steeped in tradition, however, were slow to accept scientific explanations of gypsum properties. As a result, gypsum manufacture has developed into a modern industry only in the last few decades.

Gypsum refers to the dihydrate form of calcium sulfate. Anhydrite, the other principal calcium sulfate mineral, has a very limited use, to the point that separate statistics for it are not always kept but are usually included with those for gypsum.

Although often found in close association, gypsum and anhydrite have important chemical differences. Anhydrite is the anhydrous form of calcium sulfate (CaSO_4), whereas gypsum is the dihydrate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) form. Two molecules of combined water

result in significant differences in hardness, density, and solubility between the two minerals; however, the most important difference is their thermal properties. Gypsum, following the application of a modest amount of heat, can be converted to the hemihydrate of calcium sulfate ($\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$; also known as *plaster of paris*), an intermediate product on which is based more than 90% of the value of all calcium sulfate end products. Anhydrite, on the other hand, is inert at these temperatures, and its uses are limited to those few cases where calcium sulfate in the anhydrous form has an advantage.

The first known utilization of gypsum in the United States was as a fine ground material for a soil conditioner at about the time of the American Revolution, in the late 1700s. Since that time, the term *land plaster* for ground gypsum has remained in use. Another cementitious material—lime or calcium oxide—was the preferred material for plastering, but by about 1870 a method for retarding gypsum plaster from setting quickly was discovered. Today gypsum has replaced lime almost completely as a plastering material.

In recent years, gypsum products sold in the United States reached a total valuation of approximately \$2.7 billion per year, as illustrated in Table 1.

STRUCTURE OF THE INDUSTRY

The gypsum industry is well developed in technologically advanced countries such as the United States, Canada, Western Europe, and Japan, where it is organized into large, well-financed, vertically integrated companies. In countries where gypsum usage is not as extensive, its production usually is accomplished by small operators with limited objectives and capabilities. Several North American and Western European companies operate on an international basis through subsidiaries or other arrangements. Western European companies in particular have significantly increased their international presence in recent years with the new global economy.

In 2002, 25 companies operated 50 mines that mined and/or processed gypsum in the United States. These range in size from large, multiplant, multiproduct companies to small, one-plant, one-product companies serving local markets for portland cement (as a retarder) or for agricultural gypsum. More than 75% of the gypsum was mined by 6 companies at 30 mines. Eight companies have calcining and wallboard manufacturing facilities, and the remaining 17 ship only uncalcined products. In 2002, the United States had 61 active calcining and manufacturing plants (Olsen 2002).

The larger companies are completely integrated—from mining and processing to marketing and distributing the finished products.

* Data may not add to totals shown because of independent rounding.

† Includes weight of paper, metal, or other materials.

As the importance of wallboard has grown, some companies also have built paper mills to supply part or all their needs for face and back paper used on the board. This trend toward vertical integration has resulted in strong competition and the continuing need to control all phases of the business. As a consequence, there is practically no market for supplying crude gypsum rock to calcining–manufacturing companies.

World Trade

World trade in gypsum consists primarily in the movement of crude gypsum rock, although, to a limited extent, certain manufactured products do move across international boundaries. The United States is both the world's largest producer and importer of gypsum rock. Canada is the largest exporter of gypsum, almost all of it in the form of crude gypsum rock to the United States. In 2002, Canada was the third largest producer of gypsum rock.

In Western Europe, Spain is both the largest producer and exporter of gypsum; the country's exports are in the form of crude gypsum rock. Germany, France, and the United Kingdom also produce significant quantities.

Iran was the second largest producer of natural gypsum in 2002 and accounted for around 90% of Middle Eastern output (Olsen 2002).

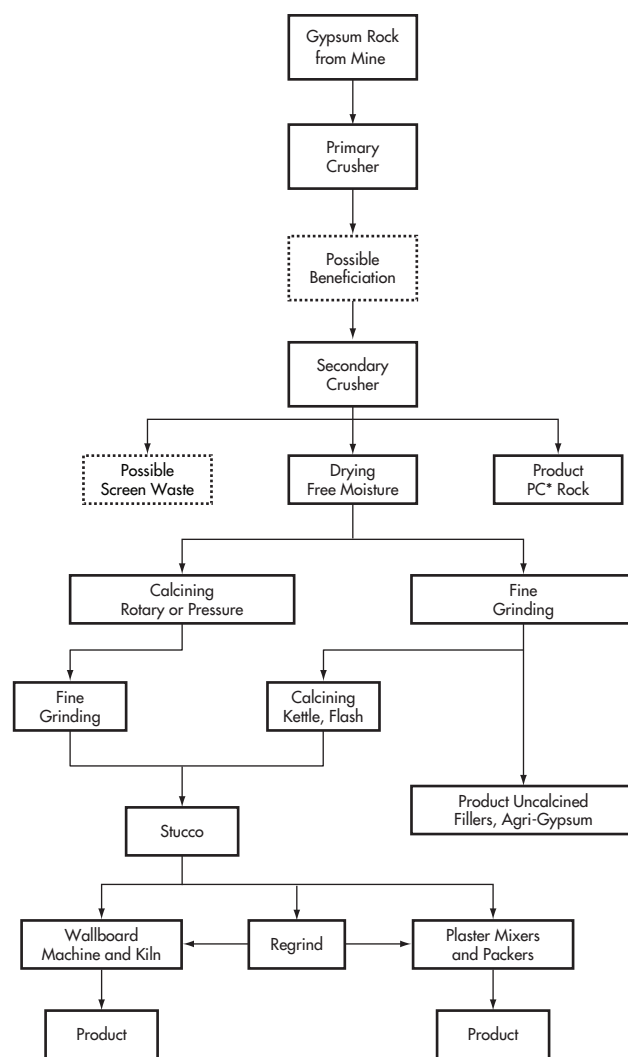

The primary reason for the limited amount of world trade in gypsum or its products is the widespread occurrence of deposits and in the relatively low ratio of manufacturing costs to product weight. Freight, therefore, is a major segment of delivery cost, a fact that discourages shipping gypsum long distances across international boundaries. For further discussion on the occurrence and place value, and for statistics on U.S. imports, the reader is referred to the Gypsum and Anhydrite chapter of this book.

BASIC PROCESSING METHODS

The processing of gypsum can be divided into three basic steps: (1) rock preparation, (2) calcining, and (3) formulating and manufacturing. This is illustrated graphically with the flow chart in Figure 1. The specifics of each step will vary with the quality of the gypsum and with the type of final product.

Rock Processing

Primary crushing is accomplished by gyratory, jaw, roll, or impact crushers, depending on the size of the mine-run rock, the desired throughput, and the type of subsequent processing. Secondary

*PC = portland cement

Figure 1. Gypsum process flow block diagram

crushing is done with a variety of standard units, but hammer mills, roll-type, and cone-type crushers are most commonly utilized. Fine grinding of uncalcined gypsum is generally accomplished by air-swept roller mills fitted with integral air separators for better particle size control, although high-energy impact mills with air classifiers also have been used.

Both primary and secondary crushing steps usually are conducted with vibrating screens in the circuit, in part to maximize crushing efficiency and to reduce the production of ultrafines, but also to recover portland cement rock, which is the first marketable product of gypsum processing. The particle size of portland cement rock will vary with the requirements of each individual cement plant, but in the United States, it most often falls within a range of 38 to 51 mm top size by 6 to 13 mm bottom size.

Drying (the removal of free moisture) may occur either before or after the secondary crushing stages, depending on the amount of free moisture in the mine-run rock. Because 5-mm crushed gypsum is difficult to handle, particularly if wet, drying often is required to ensure the free flow of material in subsequent steps. This is accomplished most often in rotary dryers and must be carefully controlled so that the temperature of the rock does not exceed 49°C, the point at which dissociation of combined water begins to take place.

In many cases, the purity or quality of mined gypsum is sufficiently high that it can be used without upgrading; however, beneficiation techniques are sometimes employed to meet the required specifications. The most common form of beneficiation is simple classification by particle size with dry screening, air separation, or other means wherein a size fraction containing a significant portion of impurity is discarded. In general, this method is used to reduce clay and/or sand (soil) impurities. In some cases, impurities, which are harder than gypsum and which tend to concentrate in coarser size fractions after crushing, also can be reduced by screening.

Washing and/or wet screening is used in a few cases, particularly where the need for whiteness exists. The use of gravity separation with high-density media for the removal of impurities currently is employed at two operations in Canada. In many cases, gypsum is amenable to other gravity methods of beneficiation, froth flotation, or to color sorting. Some laboratory work has been reported on these approaches (MacPherson 1950; French 1967). Their relatively high cost and the availability of high-quality deposits of natural gypsum and sources of synthetic gypsum, however, usually eliminate the need for these types of beneficiation.

Synthetic Gypsum

Over the last 25 years, the use of synthetic gypsum has gained in popularity. It often replaces natural gypsum and is used as feedstock in greenfield plants, particularly in industrialized nations. Today, about 25% of the gypsum consumed for wallboard manufacture in the United States is from synthetic sources. Its use is expected to continue to grow over the next 10 to 15 years. The availability of synthetic gypsum is lowering barriers for competing manufacturers entering new geographical markets.

Synthetic gypsum originates from several industrial processes. Mainly, it is a product resulting from industrial acid neutralization, or flue gas desulfurization (FGD), of fossil fuel combustion in power plants and can be as pure as 98% $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$.

By far the largest amount of synthetic gypsum is obtained from the production of wet phosphoric acid from phosphate rock. But high levels of impurities and often low levels of radon render phosphogypsum useless or reduce it to insignificant levels. Other sources of synthetic gypsum include small quantities from the production of organic (e.g., citric, lactic, tartaric, and oxalic) and inorganic (e.g., boric) acids.

Today, it is common to use synthetic gypsum from FGD for wallboard manufacture. Its ever-increasing availability is a result of environmental regulations such as the Clean Air Act Amendments of 1990.

Synthetic gypsum usually is available in its granular form (30 to 60 μm), with moisture content varying from 6% to 15%. The product normally is dried by the consumer to less than 1% moisture content prior to calcining and then handled in the same manner as natural gypsum throughout the manufacturing process. The major advantage of using synthetic gypsum is its low cost, so it is a matter of economics. The cost of transportation is usually the determining factor. As requirements for reducing sulfur dioxide emissions are implemented throughout the power-generating industry, the availability and use of synthetic gypsum are likely to increase in the foreseeable future. The Flue Gas Desulfurization chapter in this volume contains additional information.

Calcining

In the gypsum industry, calcining reduces the dihydrate of calcium sulfate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) to the hemihydrate ($\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$) or anhydrous (CaSO_4) forms. In the very early history of making gypsum plaster, pieces of gypsum rock simply were heated in an open wood fire to bring about dehydration. Then crude ovens were built, into which fist- or head-size particles of gypsum were calcined, and, later, vertical kilns were used. The latter still may be found in less technically developed countries, operating with crude burners, and with little or no prior preparation of the rock. Where the utilization of calcined gypsum has developed on a broad scale, more sophisticated methods of calcination have evolved that require preparation of the gypsum as previously described.

Hemihydrate

Considerable research has been performed on the thermodynamic properties of the $\text{CaSO}_4 \cdot \text{H}_2\text{O}$ system (Kelley, Southard, and Anderson 1941; Riddell 1950), and therefore extensive literature exists in this regard. Four calcined products are manufactured on a commercial scale: the two forms of hemihydrate (alpha and beta); a soluble anhydrite; and an insoluble or dead-burned anhydrite. Within the industry, all the hemihydrates usually are called *stucco* regardless of how they are processed, but this term should not be confused with the portland cement and sand mixture used for exterior application on buildings. The term *plaster of paris* often is used for hemihydrate; its origin comes from the large deposits of gypsum that were mined from under and near the city of Paris.

Hemihydrate is the only lower hydrate of calcium sulfate for which an identity has been established with any degree of certainty (Riddell 1950). Although two forms of hemihydrate—alpha and beta—have been identified, the beta form has a higher energy content and a higher solubility rate. The two forms can only be distinguished by sophisticated analytical methods. The alpha form of hemihydrate is less reactive than the beta form and has a slower rate of strength development. These are disadvantages when used for stucco; nevertheless, rehydrated alpha hemihydrate makes a denser, stronger plaster, which is advantageous in other uses. Table 2 gives the principal characteristics of these two forms of hemihydrate.

Alpha hemihydrate can be prepared by dissociation of gypsum in a water-saturated environment above a temperature of 97°C. This usually is accomplished at an elevated pressure in an autoclave in the presence of steam. Beta hemihydrate can be prepared by dissociation of gypsum in a vacuum at 100°C, but in practice it is done in an undersaturated environment at atmospheric pressure.

The greatest use of calcined gypsum is in the manufacture of wallboard and the formulation of plasters for building markets.

Table 2. Characteristics of alpha and beta hemihydrates

Type	Normal Consistency*	Setting Range, min†	Typical Set Expansion, %	Average Compressive Strength, kPa, Dry†	Reaction
Alpha	30–45	15–25	0.30	38,000	Neutral
Beta	64–76	10–20	0.20	14,000	Neutral

* Parts water to 100 parts stucco by weight to make a pourable slurry.

† Per ASTM C472-99(2004).

Figure 2. General sections of a calcining kiln

Beta hemihydrate gypsum is suitable for construction applications where early high-strength development is necessary. Because alpha hemihydrate makes a denser, higher-strength cast, it is preferred for industrial uses where these characteristics are important. Other factors considered in the utilization of these two forms are cost (beta is considerably less expensive to make) and water demand (alpha requires less water, above that which is necessary for rehydration, to make a slurry of equivalent consistency or viscosity).

Although other methods of calcining gypsum are gaining in popularity, the kettle is still the most commonly used vessel. Its basic design originated around 1870, and its general features are illustrated in Figure 2. In its simplest form, the kettle is a cylindrical steel vessel with a height greater than its diameter, and is enclosed in a refractory shell (Figure 3). Heat is introduced in a firebox below the vessel and flows upward around it. To improve heat transfer to its pulverized gypsum contents, four or more horizontal cross-flues are installed. The gypsum is agitated by means of a vertical, rotating shaft with sweeps or rabble arms that stir the con-

Figure 3. Exterior view of gypsum kettle

tents. Normally operated in continuous mode, the kettle is filled from the top, and the overflow is directed through a side opening in the kettle. The kettle also is used in batch mode for plaster products, especially in the United States.

For the production of stucco in wallboard manufacture, pulverized gypsum (land plaster), with a fineness of about 90% of –100 mesh is metered into the kettle at a constant rate by a screw or rotary feeder supplied through a large bin. Continuous kettles discharge finished stucco through an overflow apparatus connected to the hot pit or product bin. As fresh, cool land plaster enters the kettle top, it sinks through the hot, less dense, calcining mass, forcing calcined stucco out through the overflow pipe as a result of this density displacement. Stucco typically is discharged from the continuous kettle at 138 °C to 154 °C. One variant on the continuous kettle is the use of submerged combustion where the process takes place inside the kettle shell, resulting in better energy efficiency but producing a more violent calcination.

A kettle is run in a batch mode to produce stucco with high plasticity, high strength, and high density—characteristics that are desirable for construction and industrial plaster. The full cycle from filling to dumping the batch requires 1.5 to 3 hr. Although kettles have been built for 1.8- to 27-t capacity, the normal size is 10 to 18 t. A normal cycle requires 25 to 40 min to fill the kettle and an additional 90 to 120 min to bring the entire mass up to the desired temperature after the kettle is filled. Dumping is usually accomplished in 5 min or less, with the finished stucco being fed by gravity through the dump gate into the vented hot pit where it is held for up to 1 hr to allow as much of the entrapped steam as possible to escape before it is transferred to a storage bin at the point of use.

During calcining, gypsum begins to lose its water of crystallization when it reaches a temperature of 43°C to 49°C. During the

filling part of the cycle when gypsum is filling the kettle, the firing rate is controlled to keep the kettle contents at a temperature of about 100°C. When the kettle is filled, the firing rate is adjusted accordingly; different firing rates will produce different properties in the finished stucco. As the temperature of the mass rises, water of crystallization is released as steam, and at 116°C to 121°C the mass boils vigorously as the vapor pressure of the released steam reaches atmospheric pressure. When boiling ceases and little or no steam is released, the contents of the kettle settle to about 85% of its original volume. This quiet period indicates that most of the gypsum particles are dehydrated to the hemihydrate form. Heating continues to dry the mass until its temperature reaches 149°C to 166°C, at which point it is dumped into the hot pit and the cycle is complete.

The product of the foregoing operation is known as *first-settle stucco*, and it contains from 5% to 6% combined water, compared with 20.9% contained in pure gypsum; approximately 75% of the water of crystallization is driven off. Because this reaction takes place at atmospheric pressure in an undersaturated environment, most of the resulting hemihydrate is in the beta form.

Aridized stucco refers to first-settle stucco to which a small amount of a soluble salt is added during the filling part of the cycle. In general practice, approximately 0.68 kg of calcium chloride (CaCl_2) is used per ton of stucco; the exact amount depends on the purity of the gypsum rock and what impurities are present. This treatment increases the vapor pressure in the kettle, allowing the calcination to occur at a lower temperature. The resulting stucco is used in the formulation of many industrial plasters.

Low-water-demand stucco also can be produced by adding water to the kettle after the batch calcination cycle is complete. The stucco is quenched to about 93°C and then reheated to drive off excess water before dumping it into the hot pit. Alternatively, low-water-demand stucco can be made by adding a measured amount of water to the stucco after it has left the kettle.

Other methods have been utilized in the production of beta hemihydrate. Jacketed hollow-flight screw conveyors have been limited use. The hollow-flight screw and jackets are filled with circulating heated liquids or gases. In recent years, flash calcination techniques have gained in popularity, especially with the rising use of synthetic gypsum. Air-swept heated impact mills are becoming more commonly used for calcining, because they can readily accept fine and coarse rock or synthetic gypsum feedstock. Flash calciners that concurrently grind and calcine gypsum rock are becoming popular as well.

Flash calcining in a hot air stream with subsequent separation in a cyclone or baghouse dust collector can be done either after or in conjunction with final grinding. High-temperature hammer mills or roller mills have seen increased use as hot air-swept grinder-calciners for efficient stucco production. These mills typically are fed 50-mm gypsum rock. In some parts of the world, the rotary kiln still is used for calcination, especially for construction plasters, but in the United States these have been replaced almost totally by kettle or flash calciners.

Pressure calcining in steam autoclaves, with or without the addition of a crystal modifier, is used to make high-strength plasters for certain industrial uses. The gypsum may be introduced into the vessel either as a crushed, sized rock or as a slurry; the stucco is dried as soon as calcination is completed. This method produces all alpha hemihydrate and is relatively expensive. Its use is limited to those products requiring high-strength specialized plaster. Alpha hemihydrate also may be produced by dehydration of gypsum in hot, salty water.

Soluble Anhydrite

If desired, a second-settle stucco can be made after reaching the first boil and first-settle stages. This is done by increasing the temperature to about 177°C, the point that gypsum again starts to boil and give off steam. This second boil is of shorter duration and less vigorous than the first, because there is a smaller percentage of water of crystallization to remove. The batch material is dumped at about 210°C, the point at which almost all the water of crystallization has been removed. The dumped material usually is referred to as *soluble anhydrite*. It differs from first-settle stucco in that it has less plasticity, but after rehydration it has a greater density and strength. Also, it has a high affinity for moisture and is utilized as a desiccant.

Insoluble Anhydrite

Dead-burned gypsum, or insoluble anhydrite, is made in beehive kilns, rotary calciners, or flash calciners using high temperatures (up to 540°C). The result is anhydrous calcium sulfate that does not rehydrate at any appreciable rate; it is the least soluble form of calcium sulfate (Riddell 1950). The primary uses for dead-burned gypsum are to make Keenes cement (chemical accelerators are added to restore its setting properties) and to produce a mineral filler by fine grinding.

Hydraulic gypsum refers to lump (25 mm) gypsum that is heated to about 899°C, the temperature at which calcium sulfate begins to dissociate, releasing sulfur as sulfur dioxide (SO_2) gas. This increases the calcium oxide (CaO) content, resulting in a material which, when mixed with water, is slow-setting compared to other plasters. It provides a very hard, dense product that is quite durable, sometimes referred to as *Estrich gypsum* (a German term). Although it has been used in Europe as flooring material, it has not found an application in the United States.

Formulation and Manufacturing

Calcined gypsum products commonly undergo additional processing such as cooling, grinding, mixing with additives, or rehydrating and casting into block or wallboard. Kettle stucco, the most common calcined material, is a mixture of calcium sulfate particles in varying states of dehydration ranging from dihydrate to anhydrous forms; the forms vary according to the method of calcination. The amount of variation is minimized by carefully controlling the calcining process, which may be a factor in the type of treatment subsequently applied to the stucco.

The earliest attempt at formulating calcined gypsum to improve its utility probably was the addition of fibers and/or aggregates; however, the single most important discovery was that the setting time could be either retarded or accelerated to very exact rates by adding certain materials to stucco (plaster of paris). When mixed with water, properly calcined gypsum will have a natural setting (hardening) time of 15 to 25 min, which is usually too fast for satisfactory application on walls or ceilings. In the mid 1870s, a method was discovered that retarded the setting to 2 or 3 hr (or longer). This led to the manufacture of "slow-set plaster," which was the key to the rapid growth of the use of gypsum in the U.S. building industry. Retarders are made from organic compounds from several different materials. For the most part, these are formulated and manufactured by the major gypsum companies for their own consumption. Accelerators can be natural or synthetic salts, such as potassium sulfate, or gypsum itself. Finely ground raw gypsum is commonly used to accelerate the set of stucco for the manufacture of wallboard.

With the correct proportions of these materials, gypsum plaster can be accelerated to set within 2 to 3 min, or be retarded so that

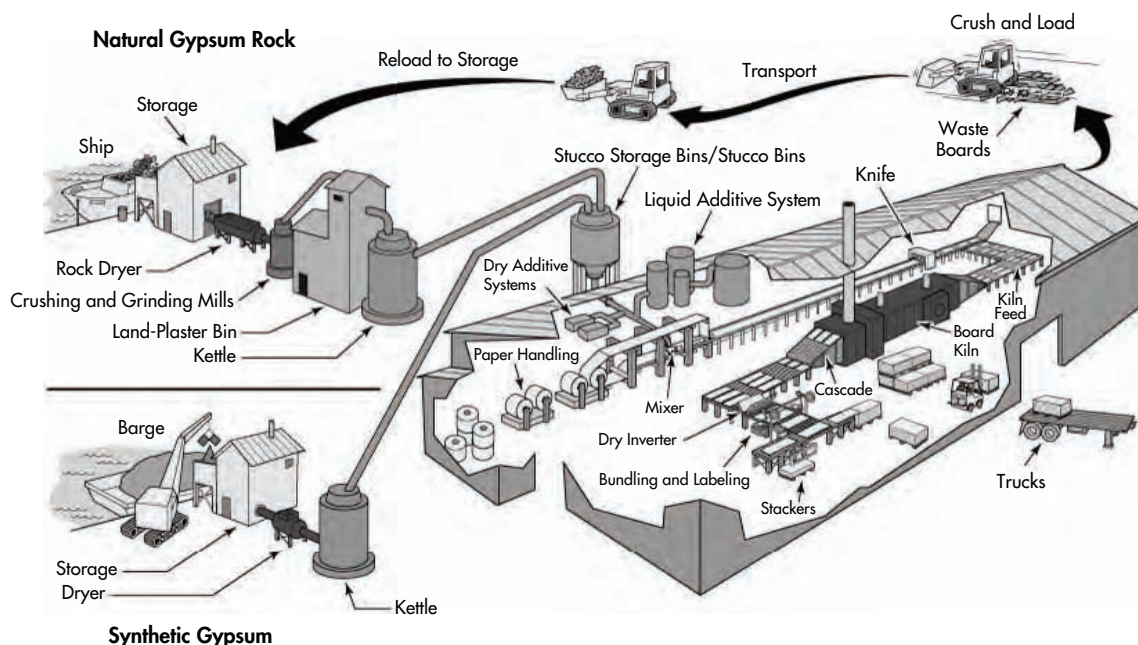

Figure 4. General process flow of a wallboard plant

it does not set for several hours. Adjustment of the set can cause variations in other properties, especially strength, so care must be exercised when adding these materials.

The type of stucco and the characteristics of the plaster being formulated are controlled by other additives mixed in precise proportions prior to bagging; these formulas are the result of extensive research. Plasters premixed with sand, expanded perlite or shredded polystyrene, and exfoliated vermiculite aggregates are available to the building trades; a wide range of plasters also are formulated for industrial use.

Gypsum is often re-ground after calcining to impart special qualities to the stucco. The classic buhrstone mill once used for this purpose has been replaced by high-energy impact mills. When stucco is used with aggregate (as for "sanded" or "perlited" wall plaster), a tube mill is used for regrinding. Roller mills operating in closed circuit with air separators often are used in conjunction with rotary kilns.

One of the early uses of gypsum as a construction material was to cast it into blocks or tile. Continuous casting machines were developed for this purpose along with drying kilns to hasten the removal of excess moisture. Blocks are cast either as solid masses or as hollow tiles, and can be made in any desired dimension. Metal reinforcement is used in some products, and others are cast into a metal form to produce floor access panels. The addition of fiber for reinforcement is a common practice; the use of an accelerator hastens the initial set of the stucco in the mold.

The largest use for gypsum today is in the manufacture of wallboard; nearly 90% of the gypsum consumed in the United States is used for this purpose. In its simplest form, wallboard is a thin, flat slab of formulated gypsum made by casting a slurry of stucco and water in a paper envelope; that is, a gypsum core with specially prepared paper bonded to both sides and edges. This is a sophisticated product, made on high-speed, highly automated machines to a wide range of precise specifications.

The bond between the paper and the gypsum core in wallboard is produced by the growth of gypsum crystals into the fibrous pores of the paper as the stucco is rehydrated, and not by the use of adhesives. Although significant research has determined the formulas for the gypsum slurry used in wallboard, it essentially consists of beta hemihydrate, an accelerator, fibers, starch, and a foaming agent, with stucco making up at least 95% of the material used prior to mixing with water. Figure 4 shows a general process flow diagram of a wallboard plant.

In the wallboard-manufacturing process, the dry components are mixed with water in a high-energy mixer designed for a continuous flow-through of material. The resulting slurry is fed onto a moving strip of paper, the edges of which are turned up to form a wide, shallow trough. This batch of slurry and paper then moves under a second strip of paper, and the roughly formed board moves between edge guides (Figure 5) and under a 610-mm-diameter roller called a *master roll*, or a stationary steel forming plate, that precisely imparts the specified width and thickness of the board. The edges of the bottom paper are turned over to form square or rounded corners, and an adhesive is added to bond the top paper to the lower paper along the edges. The thickness of the board can be adjusted by raising or lowering the master roll or forming plate. The now fully formed board moves along on a flat conveyor belt several hundred meters in length.

The speed of the board line varies with the design of the machine and the type of wallboard manufactured, but it usually ranges between 0.5 and 3.0 m/sec. The length of the board line is designed to provide sufficient time (2 to 5 min) for the stucco to set. At that point the moving strip is cut at specific intervals by a rotating knife to produce individual boards for drying in order to remove excess free moisture. This is accomplished by moving them through a continuous, multideck board kiln that is heated directly by hot air, or indirectly by steam coils. Drying is closely controlled to prevent recalcining the gypsum core.

After emerging from the board kiln, the board moves automatically through devices that smooth its ends and cut it into specified lengths. Usually, one surface ("the face") is made with light colored, smooth textured paper that will form the finished (painted) wall surface. Two boards are placed with these surfaces together ("face to face") to protect them as they are bundled for shipping. If specified, the board can move onto a finishing machine where a special surface film is added, such as vinyl or imitation wood veneer paper, to make a predecorated panel. The most popular size of wallboard is 1.2 m \times 2.4 m \times 12.7 mm thick, but a wide variety of sizes is made for specific markets.

Gypsum sheathing is made in the same general manner except that asphalt-impregnated paper is used. To improve its water resistance, an asphalt or wax emulsion also may be added to the core. Plasterboard is a 406-mm-wide board used as a base for plastered walls, instead of wood or metal lath, and is made on the same machine as wallboard. Shipment of the finished products is by truck or rail. Most wallboard plants have large warehouse space at the plant in order to store adequate stocks of various product types and sizes.

Energy Considerations

The gypsum industry is energy intensive, particularly regarding fuel used in rock drying and calcining operations, in manufacturing paper, and in drying excess moisture from wallboard. An average 2.8 GJ is required per 100 m² of 12.7-mm-thick wallboard. The drying of both rock and wallboard usually is accomplished in direct fired kilns (although steam coils can be used for wallboard) in which a clean-burning fuel (preferably natural gas) is required to prevent contamination of the product. The calcination step, particularly when carried out in a kettle, requires the ability to change the intensity of the heat quickly, and either natural gas or fuel oil is preferred, although coal also can be used.

The rise in energy costs over time encouraged the development and implementation of conservation methods, including the investigation of process technology to reduce energy requirements. As a result of increasing energy prices, fuel substitution may be necessary.

Major Categories of End Uses

Gypsum products are divided into several categories based on end uses and/or processing methods. Three major groups are generally recognized: (1) construction products used directly in construction or building material, (2) industrial products used in the manufacture or processing of other materials, and (3) agricultural products. The construction group utilizes about 75% of the gypsum rock used in the United States and produces approximately 95% of total product value. The industrial group uses about 17% of gypsum production but yields only 3% of the product value. Agricultural gypsum accounts for the balance.

The amount produced for each major application varies considerably from country to country, and in many instances the only use of gypsum is in the industrial category as portland cement retarder. In the following section, a few of the more important end uses will be reviewed.

Construction Uses

Gypsum products are used in the building and construction industry as covering and finishing materials. They are not the structural components that provide the frame or support for a building, which are wood, steel, concrete, concrete block, and brick (fired or adobe). It is in the covering of a structural frame (Figure 6), or in the finishing of masonry walls, that gypsum products find their greatest utilization, and they compete in these applications with

Figure 5. Forming section of wallboard machine showing stucco slurry feeding onto bottom paper at forming plate

Figure 6. Installing gypsum wallboard partition using steel studs

other covering or finishing materials, such as wood, plastics, or other cementitious (cement, lime, or, in less-developed regions, even mud) products.

The favorable characteristics of gypsum that give it value in the manufacture of construction materials are its fireproofing qualities, its versatility, which comes from being able to use it in many forms, and its low cost of application. It is used entirely in its calcined form, as formulated and/or manufactured stucco in plasters, block or tile, and wallboards. In recent years, approximately 96% of the gypsum used in the United States for construction materials was in

Figure 7. Boom truck stocking a house with wallboard

Figure 8. Veneer plaster application

the manufacture of various sizes and types of wallboard, with a total surface area of some 2.8 million m² per year (Olsen 2002).

Gypsum is noncombustible, making it one of the most effective fireproofing materials known, a property owed to its combined water content. When the hemihydrate form of gypsum (stucco) is rehydrated to make a covering material, it reverts back to dihydrate, so that when heat from fire comes in contact with a plaster wall (or gypsum wallboard), it begins to lose combined water as steam, inhibiting the transmission of heat. Extensive research into gypsum's fireproofing property has resulted in products with a high fire rating—an important reason for the wide acceptance of gypsum products by the construction industry, particularly when wood framing is used.

The versatility of gypsum is also a major advantage. By the use of different calcining methods and additives, the physical properties of plaster, wallboard, and cast blocks and tiles can be adjusted to meet a wide range of requirements. This versatility gives the architect and builder many choices in design and affords them maximum flexibility to produce a structure that meets the customer's specifications.

The economics in the application of building materials usually is measured by the cost per square meter of finished wall or floor space, or of cubic meters of material. It also is a function of the cost of delivering building material to the jobsite plus the cost of installation.

The wide use of gypsum construction products is based on the industry's ability to keep manufacturing and distribution costs low, and to minimize the amount of labor in product installation. For example, the boom truck (Figure 7) was developed to decrease the amount of manual handling and also to provide delivery of gypsum wallboard directly to the jobsite.

Part of the low cost of processing gypsum during manufacture is because of its softness (2 on the Mohs scale of hardness), resulting in less abrasion. Energy costs also are kept low due to inherently low calcining temperatures. The wide geographical distribution (high place value) of gypsum deposits and sources of synthetic gypsum results in low transportation costs.

Although plastering walls and ceilings was widely practiced in the United States in the early 1900s, this has given way to drywall construction employing gypsum wallboard. Today, one-coat and two-coat veneer-type plasters (Figure 8) have been developed and applied over 1.2-m-wide plaster bases; many plasters are now formulated for machine mixing right at the jobsite and pumped to the point of application. Plastering continues to be used where special effects are desired, and its flexibility provides wide latitude in finishing design. Outside the United States, plaster is still commonly used over block wall construction.

Gypsum wallboard originally was developed in the United States. Made in about 1890, the first wallboard product consisted of four sheets of felt or paper with thin layers of gypsum stucco between them. By 1914, the development of wallboard with only a top and bottom sheet of paper, and a single gypsum layer between, had been perfected. The use of this product received a big boost in the construction of buildings during World War I. After World War II, increases in hourly wages raised the cost of plastering walls, causing the rapid expansion of gypsum wallboard, which provided lower labor requirements than the traditional two-coat plaster wall.

The present dominant position of wallboard stems not only from its economy of installation but also from the variety of applications that the industry has developed. Examples include movable partitions, enclosures for elevator shafts in high-rise buildings, and sound-rated wallboard systems for multiple-unit housing.

Other construction uses of gypsum include self-leveling floor underlayments, water-resistant sheathing, plaster baseboard, ceiling tiles, and fireproofing building steel.

Industrial Uses

Industrial gypsum can be divided into three broad categories: calcined, anhydrous, and uncalcined, each utilizing distinct properties of the mineral.

Although the industrial segment of the gypsum industry is well developed in the United States, markets are widely scattered geographically. Many product lines tend to be specialized, and, with the exception of portland cement retarder rock, individual customers are likely to want tens or hundreds of tons of product, rather than thousands of tons.

Calcined Industrial Gypsum

Perhaps the largest industrial use of calcined gypsum is for making molds for sanitary ware, pottery, metal casting, and decorative objects.

Molding plaster is made from high-purity gypsum (95% $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ or greater) at select locations and is marketed on the basis of its water demand, strength, white color, setting time, and closely controlled expansion/shrinkage qualities. It may be made from either beta or alpha hemihydrate, or a combination of the two.

High-density, high-strength plasters are used in the maintenance of floors and for quick patching of high-use surfaces (such as highways) that cannot be closed down for more conventional repairs. In this application, gypsum plaster may be mixed with other cementitious materials to obtain optimum results.

Anhydrous Gypsum

In addition to the hemihydrate industrial plasters already described, several products are made from calcium sulfate with no water of crystallization, which is from second-settle stucco made when the calcining temperature has been raised to about 200°C. This material is often referred to as soluble anhydrite.

When calcination proceeds to a temperature of 480°C, a dead-burned or insoluble anhydrite product is formed, which is used for the manufacture of Keenes cement. Dead-burning usually produces a whiter product and is preferred where color (that is, lack of color) is important. Keenes cement is a generic name for dead-burned gypsum that, with the use of additives, can be made to set and harden after mixing with water. The usual set specifications fall in the range of 4 to 12 hr. Its major use is in wall plaster where extra density, strength, and hardness are desired. Keenes cement is made in only a few locations and only in small quantities.

Uncalcined Industrial Gypsum

This category, sometimes referred to as raw gypsum, is used as a retarder in portland cement. By volume, this is the second largest use of gypsum outside of wallboard manufacturing. In 2002 (Table 1), 2.6 million t, or 8% of all the gypsum used in the United States, was consumed by this market (Olsen 2002).

It is well known that calcium sulfate compounds control the setting time of portland cement—both the rate at which the cement paste develops strength and the shrinkage of portland cement products during drying. The use of calcium sulfate compounds in portland cement has been the subject of extensive research and is standardized by the American Society for Testing and Materials (ASTM). The amount of gypsum (or gypsum-anhydrite [GA] blend) depends on: (1) the SO_3 content of the gypsum, (2) the type of portland cement, and (3) the mix of raw materials used to make cement clinker. In practice, the amount of gypsum will vary from 4% to 6%, averaging approximately 5% by weight of finished portland cement. As it is fed into the grinding mill, the gypsum is ground with clinker, and the two materials are mixed together.

The setting and strength development of portland cement is based on several complex chemical reactions. As these are better understood, raw material specifications are tightened, with particular emphasis placed on the homogeneity of the constituents. A trend toward increasing the amount of sulfur trioxide (SO_3) per unit volume of portland cement will increase the demand for a uniform grade of gypsum and anhydrite products for portland cement manufacture.

The use of anhydrite in portland cement represents the largest market in the United States for this mineral; however, it is a highly fragmented market because not all portland cement plants want anhydrite in their retarder component.

Table 3. Average gypsum prices (2002)*

Gypsum Product	Price, \$/t
Portland cement retarder	12.37
Agricultural gypsum	23.65
Plasters	150.98
Wallboard, 12.7 mm	87.02

Source: Olsen 2003.

* Based on total quantities and value of these products as shown in Olsen 2003.

Where anhydrite is used, it generally is blended with gypsum; the usual blend contains 40% anhydrite. Because many plants prefer straight gypsum to a GA blend, any one cement plant might use only 4,500 to 9,000 tpy of anhydrite. It is estimated that probably no more than 5% of the 3.9 million t of gypsum reportedly used for portland cement retarder in 1990 was the mineral anhydrite (Kebel 1994).

MINOR USES FOR CALCIUM SULFATE

The use of anhydrite to construct load-bearing packwalls and to provide support for longwall gate road steel arches in underground coal mines is practiced extensively in Germany and to a lesser degree in Great Britain and France. Anhydrite is crushed, sized, and then transported pneumatically underground to the application site. An accelerator consisting of potassium sulfate and ferrous sulfate is mixed into the crushed anhydrite, and the material is wetted during emplacement. This process produces a quick-setting, high compressive strength, monolithic material.

Prices

In Table 3, the average prices of four representative gypsum products are shown for 2002 and are typical of the wide range in value among different products. These figures correspond to the amount of processing and beneficiation of the products: the greater the amount of processing, the greater the cost to consumers. These figures represent mill net prices and are averages across the United States. Prices at any given location will vary widely from these averages, and freight and other distribution costs must be added. Delivered costs, based on list prices, are quoted for several cities in *Engineering News-Record*, which is considered an industry standard source for this information.

Table 4 shows the recent trend of gypsum prices. Gypsum prices peaked in 1999 as U.S. housing construction grew strongly and outstripped U.S. industry capacity. Additional wallboard capacity from traditional U.S. producers and new wallboard capacity from foreign-based companies entering the U.S. market began to come on-line in the late 1990s. Gypsum prices dropped correspondingly to moderately lower levels, reflecting the growth in industry capacity, while demand for gypsum products remained high into the early 2000s (Figure 9).

FUTURE TRENDS

Gypsum will continue to be widely used for years to come. As the housing boom in the United States continues, demand for wallboard is expected to grow. U.S. wallboard suppliers are meeting this need by expanding existing manufacturing plants while building high-capacity greenfield manufacturing plants as well. For some new plants, synthetic gypsum will be the normal feedstock.

In wallboard manufacture, synthetic gypsum has become an important substitute for mined natural gypsum. In 2002, synthetic

Table 4. Gypsum products price index (1982 = 100)*

Year	Index	Year	Index
1980	100.1	1992	99.9
1981	100.1	1993	108.3
1982	100.0	1994	136.1
1983	111.7	1995	154.5
1984	135.4	1996	154.0
1985	132.3	1997	170.8
1986	137.0	1998	177.6
1987	125.2	1999	208.0
1988	112.9	2000	201.4
1989	110.0	2001	156.4
1990	105.2	2002	168.9
1991	99.3	2003	171.5

**Figure 9. Producer price index of gypsum products**

gypsum accounted for 24% of the total U.S. domestic supply (Olsen 2003). The use of synthetic gypsum should continue to increase and may very well account for up to 50% of the U.S. supply within the next 10 years.

Although the most popular size and type of wallboard will continue to be the 1.2 m × 2.4 m × 12.7 mm-thick paper-clad sheet, new types of gypsum wallboard are expected to grow in popularity. For example, fiber gypsum board, a nonpaper face and back board, incorporates a homogeneous blend of gypsum and paper fiber for abuse-resistant floor underlayment applications. Another example

is a gypsum wallboard with water-resistant sheathing application that utilizes fiberglass scrim to replace the face and back paper.

Insulation

Daniel R. Hack

INTRODUCTION

The numerous products on the market used for thermal and acoustical insulation consume substantial quantities of a variety of industrial minerals.

Acoustics is the science of sound, and architectural acoustics deals with sound in buildings; most acoustical insulation, however, is manufactured for transportation vehicles. *Sound* is defined as the auditory sensation in the ear, or the disturbance in a medium which causes this sensation. Acoustical insulation is used to reduce or eliminate *noise*, which is defined as unwanted sound. Noise can be controlled by reducing sound radiation at the source, by using sound-reducing construction methods such as staggered studs and so forth to control sound transmission, or by using sound-absorbing material on walls, ceilings, and floors (Rossing 1985).

Acoustical insulation absorbs the energy in sound waves in a porous material. As the sound waves penetrate the pores, contact with the pore walls dissipates the sound waves by reducing the amplitude of vibration of the air molecules, and the sound energy converts to heat energy. Acoustical insulation is generally highly porous, 1.3 cm or greater in thickness, and has interconnected pores. Acoustical insulating materials include fibrous vegetable or mineral matter and cellular organic and inorganic material such as natural or manufactured foams (Sabine and Moulder 1979). Acoustical materials are most commonly porous boards and tiles, which are often composite materials with perforated facing. Roof insulation board and lightweight concrete also can contribute to noise absorption.

Thermal insulation is defined as material used to control the flow of heat. It can be used for heat control from low cryogenic temperatures (below -100°C) to more than $2,200^{\circ}\text{C}$ for applications such as ablative shields for spacecraft. Heat transfer occurs by *conduction*, *convection*, or *radiation*. Conduction is the transfer of heat without the movement of the conducting medium, as through a metal. Heat convection through a liquid or gas takes place by movement of the medium. Forced convection is the basis for heating and cooling equipment, using pumps or blowers to transfer the thermally conditioned fluid. Free or natural convection occurs because of density differences in the fluid. Radiation is the transfer of energy in space (Eckert 1985).

Insulating the body with foams, fibrous material, or small-celled granular material reduces heat conduction through a solid. Heat transfer through a gas (convection) is controlled by creating many small pores that inhibit movement of the fluid, substituting a

gas of low thermal conductivity, or evacuating the space. Heat radiation can be reduced using materials that reflect or absorb the energy (Glaser 1967). Thermal insulating materials can be vegetable or mineral fibers, organic or inorganic particles, or foams with small pores, generally used to form a low-density thermal barrier. They can be blocks, poured lightweight cementitious materials, and bricks, among others.

RAW MATERIALS AND PRODUCTION

Industrial minerals and rocks commonly used in acoustical and thermal insulations are perlite, pumice, vermiculite, clays, silica, and diatomite (Coombs 1989). These and other raw materials are used to produce common insulation varieties such as calcium silicate, glass fiber, rock wool, and refractory insulation. Other, less common varieties are ceramic fiber, foamed metal, and cementitious foam insulation.

Calcium Silicate Insulation

Calcium silicate insulations comprise industrial minerals, hydrated lime, and a silica source such as ground silica, diatomaceous earth, or perlite ore. These raw materials are discussed in more detail in this section. Small quantities of organic or inorganic fibers are added as reinforcement. In 2003, there were 90 plants that produced lime in the United States (Miller 2004). The silica source for calcium silicate thermal insulations can be finely divided silica from sandstone, quartzite (i.e., quartzose rock used to make silica flour), perlite, or diatomite.

Producing calcium silicate insulations is relatively straightforward. Hydrated lime, the silica source material, reinforcing fibers, and water are mixed and reacted at an elevated temperature. The slurry is then pumped to molds and pressed to remove water and form the finished part. The product is then autoclaved for completion of the chemical reaction and oven dried.

Thermal insulating products made by this process are pipe covering, blocks for the insulation of pressure vessels, etc., and low-density structural sheets used for paneling on ships, chutes for the conveyance of molten aluminum, and other specialty items. Calcium silicate insulations are classified as Type I for service temperature to 649°C and Type II for service to 871°C (ASTM 2004a). Service temperature is the maximum temperature at which a material can be used for the given application. Above this temperature, the material degrades rapidly.

Diatomite

As previously noted, diatomite is used as a silica source in producing calcium silicates. Diatomite can be more reactive in the hydrothermal chemical reaction with lime than silica flour because of its high surface area and its amorphous nature. Other uses of diatomite as insulation include insulation in safes and fireproof filing cabinets. It has been used as loose-fill insulation, but these applications now are limited because of loose diatomite's dustiness and subsequent health concerns. Details on diatomite are provided in the Diatomite chapter in this book; a brief review of its origin and production is given here.

Diatomite is a rock composed of siliceous skeletal remains of diatoms, which are algae that lived in salt or fresh water. It is usually 85% or more amorphous silica, with bound water, alumina, iron, and other minor constituents. It generally is mined by open-pit methods, and the production of natural (uncalcined) grades consists of crushing, drying, and classification by cyclones and separators. The United States is the largest producer and consumer of diatomite with domestic production estimated at 624,000 t (689,000 st). In 2003, seven companies were producing diatomite in four states with a total of 13 processing facilities. California and Nevada accounted for 70% of U.S. production in 2003 (Dolley 2004a). Between 2002 and 2003, production decreased by less than 1%, and its value increased by less than 1%. The next largest producing countries in 2003 were (in decreasing order of production) China, Denmark, Japan, the former Soviet Union, France, and Mexico. Insulation applications accounted for just less than 4% of domestic production in 2003, and insulation uses accounted for 17% of total global production. Average price per ton for insulation in 2003 was \$35.71 (Dolley 2004b). The diatomite market should remain stable over the next several years, and the export market is expected to strengthen as more uses, particularly as a filtration medium, are implemented.

Industrial Sand

The mineral quartz (SiO_2) is the predominant component of industrial sand. The term *PV* contains two primary subsets of products: silica flour and ground silica. Ground silica is used as a functional filler and pigment extender in many industrial products and is also the major batch component in the production of continuous strand fiberglass. Silica flour generally is sold into lower-value markets, whereas ground silica is generally sold into higher-value markets. Details on industrial sand are provided in the Industrial Sand and Sandstone chapter in this book; a brief review of its origin and production is included here.

The five leading producers of industrial sand in the United States are, in descending order, Unimin Corp.; U.S. Silica Co.; Fairmont Minerals Ltd.; Oglebay Norton Industrial Sands, Inc.; and Badger Mining Corp. Domestic production is dominated by Wisconsin, Michigan, Indiana, and Ohio, with a combined production of 9.62 Mt in 2003. These four states comprise more than one third of domestic production (Dolley 2004c). This area is also where the highest quality industrial-sand deposits are located. These deposits usually contain less than 20% deleterious materials (Pettijohn, Potter, and Siever 1987) and are contained within the Midcontinent marine quartz arenites. Significant production also occurs in California, Texas, Oklahoma, New Jersey, and North Carolina, though these sands are generally of lower quality than sands produced in the Midwest. In 2003, the average selling price in the United States for PV used in fiberglass was \$37.37/t. The provinces of Quebec, Ontario, and Alberta are the primary producers of industrial sand in Canada (Dumont 2001). The leading recipients for U.S. exports in 2003 were, in descending order, China, Canada, Mexico, and Japan.

Leading global producers, after the United States, were Slovenia, Germany, Belgium, France, and Spain. Because of recycling and substitution, the overall demand for industrial sand may decrease; the value of the production may increase, however, because of higher selling prices for value-added products such as PV.

Economic industrial sand deposits are market driven, so physical exploration techniques vary, depending on site conditions and end use. The most important element of exploration is collecting clean, unoxidized samples. Industrial sand mining methods depend on the type of deposit. Some unconsolidated deposits are mined using front-end loaders, scrapers, or bulldozers; others are mined using dredges or draglines. At well-consolidated deposits, conventional drill-and-blast methods are used. Although uncommon, underground mining also can be used to extract competent, well-lithified sandstone or quartzite. Processing distinguishes industrial sand from common construction sand, and differentiates the various uses of industrial sand. Regardless of markets, sands are, at a minimum, washed, dried, and screened. Material for high-purity products is acid leached; PV is chemically treated for some applications.

PV products also are used as the primary aggregate in both shape and monolithic-type refractories to provide high-temperature resistance to acid attack in industrial furnaces. Surface-modified PV (chemically treated) and uncoated PV are used as functional filler to modify the physical properties of a product (e.g., altering the thermal characteristics of a product).

As with many other raw materials used in insulation manufacture, health considerations are expected to have a significant effect on the industrial sand business. Regulatory agencies such as the U.S. Occupational Safety and Health Administration (OSHA) are working to lower the personal exposure limit (PEL) for respirable silica. This will have a significant effect on the building materials and recreation market segments, where limestone could replace industrial sand. To reduce or eliminate the amount of unreacted crystalline silica in the end product, finely divided (baghouse) perlite ore is sometimes used as the silica source in producing calcium silicate insulations.

Perlite Insulation

Perlite is discussed in a separate chapter in this book, so only a brief overview is given here. Perlite is a naturally occurring volcanic rhyolite glass, most commonly found in domes and flows of Tertiary or Quaternary age. Perlite volcanic glasses occur within high-silica (71 to 75 wt % SiO_2) volcanic domes, lava flows, and welded ash-flows. It is composed primarily of aluminum silicate, forms from the hydration of obsidian, and typically contains 2% to 5% water (Breese and Barker 1994). Perlite deposits are widespread in the western United States. New Mexico is the leading producing state, with commercial production also in Arizona, California, Colorado, Idaho, Nevada, Oregon, and Utah. Major foreign producing countries (in decreasing order) are Greece, Japan, Turkey, Hungary, and Mexico. The amount of domestic (U.S.) processed crude and expanded perlite produced and consumed decreased by about 5% from 2002 to 2003 (Bolen 2004). The decrease could be attributed to increasing imports coupled with weak demand from some construction markets. Perlite expanding plants mostly in the eastern United States continued to purchase less expensive, imported perlite. Consumption of perlite for low-temperature and masonry/cavity-fill insulation was 1.1% of total perlite usage in 2003. In 2003, the average value for low-temperature insulation was \$429/t and \$359/t for cavity-fill insulation, increases of 18% and 48%, respectively, over 2002 values. Domestic consumption of processed and expanded perlite is expected to exhibit slight growth. New mine

openings coupled with increasing imports should restrain price increases (Bolen 2004).

Nearly all perlite is used in its expanded form, and finds use in a variety of thermal and acoustical insulation applications. The efficiency and degree to which perlite ore expands and the characteristics of the expanded material determine whether the perlite is of commercial quality and its appropriate markets. All mines except one in east-central Nevada are open pits. In some open-pit operations, the perlite is hard and must be drilled and blasted. In others, the perlite breaks easily and can be extracted with scrapers. The milling procedure consists of crushing, drying, and screening to produce closely sized ore grades, which are thermally expanded for various end-product uses. Some producers crush perlite at the mine whereas others crush at the plant.

Perlite is custom-blended and shipped, usually by rail, but sometimes by truck, in bulk or bags to expanders near end-use sites. Some operations have expanders at or near the plant, but most move crude perlite to expanders in various parts of the country (Austin and Barker 1995). The cost of shipping the low-density expanded perlite mandates that it be used close to the expansion facility.

The commercial value of perlite derives from the fact that when flash-heated, the contained water converts to steam, expanding the viscous glass particle. Expansion is accomplished in vertical or horizontal furnaces at approximately 870°C. Density for roof insulation board is typically 4 lb/ft³, 2 to 4 lb/ft³ for low-temperature insulation, and 6 lb/ft³ for cavity-fill insulation (Bolen 2004).

Beyond the use of perlite for producing calcium silicate insulations, another major market for perlite is in acoustical tile for residential and commercial buildings. Perlite can comprise approximately 15% of the formulation. Formed cellulosic boards, which may contain as much as 70% perlite, are used for a thermal insulating substrate for built-up roofs in commercial and industrial buildings. Another major market for expanded perlite is block fill. After a cement block or other cavity-type masonry wall is constructed, loose perlite is simply poured in to the block cavities for thermal insulation. Perlite fills the irregular void spaces without bridging. The perlite usually is treated with silicone to reduce water absorption (ASTM 2004 b). Perlite used in this manner can increase the fire rating of a block wall from 2 to 4 hr. Competitive materials for this application are vermiculite and expanded polystyrene beads and inserts. Thermal-insulating block and pipe covering is made from expanded perlite and sodium silicate or another suitable binder (ASTM 2004c).

Perlite is used as a lightweight aggregate in portland cement and gypsum plasters for exterior and interior applications, for encasement of structural steel members and placement on floor and roof assemblies, as a base for ceramic and masonry veneers and tiles, and in stucco formulations (Bodycomb and Stokowski 1994). These plasters serve as fire protection and contribute to thermal and acoustical insulation, depending on usage. As an aggregate for lightweight concrete, perlite contributes sound- and heat-insulating properties when the concrete is used as a substrate for built-up roofing, floor fill, structural decks, and similar applications. Perlite concrete is also used as a thermal insulating base for swimming pools, and as a permanent insulation and structural support for underground piping. Another use for this material is to relined existing chimney flues to prevent damage to mortar.

Small particle size perlite expanded to a very low density is used as cryogenic insulation in storage tanks and vessels containing industrial gases such as liquid natural gas, hydrogen, oxygen, helium, and nitrogen, which are stored and transported at very low temperature. The annular space in a double-walled vessel is pneumatically filled with perlite and then air is evacuated from the cavity

for thermal insulation. Portable expanders frequently are used at the jobsite to expand the perlite for cryogenic use. One of the few uses of perlite ore is as ladle topping in foundries. Added to pouring ladles, perlite acts as a slag coagulant and forms a crust on the surface of molten metal to maintain the melt temperature (Bodycomb and Stokowski 1994).

Glass Fiber Insulation

Fibrous glasses, or glass wools, are used in a wide variety of thermal and acoustical insulating applications. The major industrial minerals used in the manufacture of fibrous glasses are silica sand, soda ash, and limestone (Bodycomb and Stokowski 1994). Other raw materials are dolomite, feldspar, nepheline syenite, fluorspar, and various borates (borax, colemanite, ulexite, and szaibelyite).

Glass wools are produced by one of two methods. In the less common pot- and-marble system, the constituents are mixed, melted, and formed into marbles. These preforms are then remelted over platinum nozzles. The melt, passing through the nozzle, is drawn into continuous filaments or formed into discontinuous fibers by steam or, more commonly, by flame attenuation. Generally, however, insulating glass wools are produced by melt-spinning or centrifugal spinning. The glass melt is introduced into a bowl, or inner centrifuge. The melt exits through apertures in the bowl and enters a second-stage centrifuge. Fiberization takes place when the material exits through holes in the second-stage centrifuge (Jarvela, Pohjonen, and Tormala 1990). The glass fibers bond with organic resin binders. Glass wool products are rated for use at temperatures as high as 538°C when phenolic binders are used, but most products are designed for use at lower temperatures.

Glass fiber products are tested exhaustively not only for thermal and acoustical insulating performance but also for fire resistance, flame spread, smoke generation, corrosivity, water absorption, resistance to fungus, physical strengths, and so forth. Table 1 gives some applicable test methods, designed by the American Society for Testing and Materials (ASTM). Numerous government, Underwriters Laboratory, and other testing laboratory specifications may apply.

Fiberized glass is ubiquitous as a material in building applications. Fiberglass batt, blankets, rolls, and loose-fill insulation (insulation produced as shreds, granules, or nodules that typically are blown into building cavities using special equipment) find common application in insulating buildings of all types, for both thermal protection and sound control. Batting and rolls come with or without vapor-retarding facings, which resist the movement of moisture to cold surfaces where it could condense and cause water damage to the building. Ease of installation by semiskilled labor contributes to the use of glass fiber in new and retrofit residential construction. A recent development is to encapsulate light-density batts in plastic sheathing for a product that is easier to handle and has less associated dust (K. Schaal, personal communication). Fiberized glass is also important in air handling and in HVAC systems, where duct board, duct wrap, and duct liners are used for temperature and acoustic control. Fiberglass blankets used in HVAC systems are subject to requirements for corrosiveness, moisture vapor sorption, fungi resistance, temperature and erosion resistance, odor emissions, surface burn characteristics, thermal conductivity, and sound absorption coefficients.

Other common applications are acoustical control for office cubicles, acoustical and temperature control in household appliances, temperature control and flame resistance in aircraft, and various thermal and acoustical applications in the automotive and marine industries. Newer applications are fiberglass blanket bonded with melamine resin used to insulate cryogenic tanks; a number of

Table 1. ASTM specifications and test methods applicable to glass fiber insulation

Test No.	Test Name
C-335	Standard Test Method for Steady-State Heat Transfer Properties of Horizontal Pipe Insulation
C-356	Standard Test Method for Linear Shrinkage of Preformed High-Temperature Thermal Insulation Subjected to Soaking Heat
C-411	Standard Test Method for Hot-Surface Performance of High-Temperature Thermal Insulation
C-518	Standard Test Method for Steady-State Thermal Transmission Properties by Means of the Heat Flow Meter Apparatus
C-547	Standard Specification for Mineral Fiber Pipe Insulation
C-553	Standard Specification for Mineral Fiber Blanket Thermal Insulation for Commercial and Industrial Applications
C-585	Standard Practice for Inner and Outer Diameters of Rigid Thermal Insulation for Nominal Sizes of Pipe and Tubing (NPS System)
C-612	Standard Specification for Mineral Fiber Block and Board Thermal Insulation
C-795	Standard Specification for Thermal Insulation for Use in Contact with Austenitic Stainless Steel
D-257	Standard Test Methods for DC Resistance or Conductance of Insulating Materials
D-638	Standard Test Method for Tensile Properties of Plastics
D-790	Standard Test Methods for Flexural Properties of Reinforced and Unreinforced Plastics and Electrical Insulating Materials
D-792	Standard Test Methods for Density and Specific Gravity (Relative Density) of Plastics by Displacement
D-828	Standard Test Method for Tensile Properties of Paper and Paperboard Using Constant-Rate-of-Elongation Apparatus
D-3679	Standard Specification for Rigid Poly Vinyl Chloride (PVC) Siding
E-84	Standard Test Method for Surface Burning Characteristics of Building Materials

E-136	Standard Test Methods for Behavior of Materials in a Vertical Tube Furnace at 750°C

filtration uses (liquid–gas separators, liquid–liquid coalescers, and oil and gas coalescing, among others); and microfibers (glass fibers having diameters ranging from less than 0.05 μm to 2.5 μm) in clean-room applications and for filtering blood particles (K. Schaal, personal communication).

Mineral or Rock Wool Insulation

Mineral, rock, and slag wools are synthetic inorganic insulating materials composed of vitreous glass fibers. The term *mineral wool* designates a silicate–glass–wool insulating material. They range in color from white or green to brown or black and have slag (generally an iron blast furnace slag) as the primary raw material. Rock wools use naturally occurring rock as the raw material. Slag wool designates a product made from slag and is synonymous with the present usage of mineral wool.

Historically, Illinois and Ohio dominated woolrock production (Lamar et al. 1934) with additional production in California, Indiana, Kentucky, Minnesota, Pennsylvania, Washington, and Wisconsin (Thoenen 1938). The mined units generally were argillaceous limestones and dolomites, sometimes along with quartzites, shales, granites, and other rock types used as additives. Woolrocks also occur in Alabama, the Carolinas, Kansas, Mississippi, West Virginia, and Virginia (Gonge 1931; Logan 1932; Plummer 1937; Morse and McCutcheon 1945).

Subwoolrocks, more common than woolrocks, are carbonate rocks that are less argillaceous than woolrocks, but more shaley or

sandy. They must be mixed with a flux rock such as shale, sandstone, limestone, or dolomite to produce a mixture with the proper chemical composition for wool production. Granites, wollastonite, basalt, and peridotites also have been used as subwoolrocks or flux rocks. Slags also are used as the raw material. Iron blast-furnace slags are often used and are typically available in areas near their market. Copper, phosphate, and other slags are also suitable.

The raw materials used in wool production must be capable of melting at the lowest possible temperature that will yield a liquid with the proper viscosity for forming fibers. The fiber diameter is directly related to the acid/base ratio (on a molecular basis) in the molten glass, with values less than 1.8 yielding satisfactory diameters. An empirical rule-of-thumb regarding woolrocks is that natural rocks have the proper composition if they have 20% to 30% CO_2 (Lamar et al. 1934). The raw material must be 4 to 25 cm to forestall material from being blown out of the melting furnace and to maintain the proper draft. This is very significant to the raw materials producer, largely because of the possibility that a percentage of the smallest material will be wasted in the process.

The production of both mineral and rock insulating wool starts with melting it, generally in an unlined, water-jacketed, steel kiln. For wool rocks, melting generally occurs at about 1,400°C to 2,100°C; slags melt at 1,100°C. The energy savings that result from the lower temperature used in the latter is the primary reason that many slags are currently used. Slags also have transportation and yield advantages because they are essentially free of volatiles such as CO_2 , making transportation safer and hence more economical.

Two processes can be used to produce the wool fibers. In one process, steam at 550,000 to 690,000 pascals is blown through a molten stream of glassy raw material. The steam creates globules with fibrous tails; it is from these fibrous tails that wool fibers are produced. In the other process, the molten stream of glass is poured onto a spinning, cast-iron disc, which centrifugally forms the material into thin fibers. The wool product consists of fibers and shot. The fibers are generally 2 to 10 μm in diameter and up to several centimeters long. The shot, small spherules or teardrops of glass, is about 50 μm in diameter. Manufacturers limit the amount of shot in the product during the processing operation. The collected mineral wool fibers are either used loose or shaped into batts, blankets, sheets, or blocks with a resin (generally phenolic) binder.

Recent developments include a softer, batt-type mineral product that is denser, fits more tightly into standard wall cavities, and is more resistant to air convection thermal losses than standard fiber-glass batt products. Its thermal resistance is comparable to sprayed cellulose insulation or high-density fiberglass batts (NAIMA 2004a).

Refractory Insulation

Refractories are heat-resistant materials that line high-temperature furnaces and reactors and other processing units. In addition to being resistant to the thermal stresses and other physical phenomena induced by heat, refractories must also withstand physical wear and corrosion by chemical agents. Refractories are more heat resistant than metals and are necessary for heating applications above 538°C. Refractory products fall into two categories: brick or fired shapes, and specialties or monolithic refractories. Refractory linings are made from these brick and shapes; from specialties such as plastics, castables, gunning mixes or ramming mixes; or from a combination of either category. Many refractory products, in final shape, resemble a typical construction brick; there are, however, many different shapes and forms. Some refractory parts are small and possess a complex and delicate geometry; others are massive

and weigh several tons in the form of precast or fusion cast blocks (The Refractories Institute 2004). Refractories contain and control heat in myriad end-use applications ranging from residential fireplaces to linings for high-temperature furnaces, kilns, ovens, and boilers in a wide variety of industries. A recent trend is reduced installation costs, in part because of the increasing use of air-placed castable materials, which are composed of manufactured aggregates and cementitious binders that are chemically inert. Portland cement cannot be used because of the highly corrosive nature of cooling flue gases (The Refractories Institute 2004).

Approximately 70% of refractories are aluminosilicates, 15% are silica, and 15% are basic refractories (e.g., magnesite, dolomite, and chromite) (McMahon 2002). Although certain refractories are designated as insulating products (e.g., low-density insulating brick), all refractory products are thermal insulators because they contain and control heat.

Various raw materials are used in refractory products (Norton 1967; The Refractories Institute 2004). Fireclay refractories, including firebrick, are made from plastic and flint kaolin clays (hydrous aluminum silicates) formed and fired. High-alumina refractories, originally made from diaspore, are now primarily manufactured from bauxite and have higher service temperatures than fireclay products. Silica brick is manufactured from quartzite. Basic refractory materials are magnesite brick (magnesite) and chrome brick (chromite). Insulating (fireclay) brick has low density, achieved by adding an organic burnout material, perlite, vermiculite, or expanded clay to achieve high porosity and reduce thermal conductivity. Zircon, andalusite, sillimanite, and kyanite also are used in refractories (Crookston and Fitzpatrick 1983).

Of the 383,000 t of fireclay consumed in 2001, 146,000 t (38%) was used for firebrick; the average price reported by domestic producers was \$23.54/t. In 2002, 7 firms operated 44 pits in 7 states (Virta 2003a). Of the 4.38 Mt of Georgia kaolin produced in 2003, 258,000 t (just under 6%) were for refractory uses with an average price of \$28.57/t (Virta 2003a). Of the 9.97 Mt of bauxite consumed in 2002, 115,000 t (just over 1%) were for refractory uses (Plunkert 2003). The refractory industry continues to consolidate to become more competitive and to address asbestos liability issues. As with most other insulation materials, health and safety issues dominate current innovations.

Vermiculite Insulation

Vermiculite is the mineralogical name generally applied to that group of minerals with micaceous morphology commonly formed by the alteration of biotite and iron-bearing phlogopite. A comprehensive discussion of vermiculite is presented in a separate chapter in this book. When vermiculite particles are heated rapidly at high temperature, water molecules within the internal structure turn into steam and dramatically increase the volume: flat plates of vermiculite turn into elongated, concertina-like (vermiform) particles. The increase in volume caused by this thermal exfoliation is normally in the range of 10 to 20 times, with typical exfoliated densities up to 90 to 110 kg/m³ and as low as 50 kg/m³. In its exfoliated form, vermiculite has the low density and biological inertness comparable with expanded perlite, while maintaining a chemically active surface. Most of the vermiculite mined worldwide ultimately is consumed in the thermally exfoliated form.

Vermiculite currently is mined in at least nine countries. Over the last 15 years, producers outside the United States have dominated the U.S. market. South Africa, in particular, produced 207,345 t in 2003. Other countries currently producing vermiculite are Australia, Brazil, China, Egypt, India, Japan, Kenya, Russia, and Zimbabwe (Potter 2004). The decline in domestic production

can primarily be attributed to the closure of the Zonolite operation in Libby, Montana, in 1990, which was the major source of vermiculite in the United States. Production in the United States currently is limited to South Carolina and Virginia. Two potential new vermiculite sources are being developed in Ontario, Canada.

Exploration for vermiculite deposits is straightforward because they are the products of surface and near-surface weathering. Unlike most other ores, the value of a vermiculite ore depends on the distribution and efficient recovery of relatively large particles. Vermiculite typically is mined by open-pit methods, and milling/concentration consists of flotation using a variety of surfactants. The vermiculite concentrate is shipped to exfoliation plants near the end markets.

Most vermiculite is consumed in thermally exfoliated form. In the United States, most exfoliation is accomplished using vertical furnaces. When the concentrate is flash-heated at approximately 750°C to 800°C, bound water between the micaceous sheets explosively turns into steam, expanding the vermiculite particles. Additional water may be liberated above approximately 870°C, resulting in a weak, powdery product.

Vermiculite is used in a wide variety of thermal and acoustical insulations because of its low bulk density. Vermiculite and perlite share many similar applications. Treated with either asphalt emulsion or silicone for water resistance, vermiculite is used as cavity fill for thermal insulation in cement block and other masonry structures (ASTM 2004d). Coarser grades of vermiculite are used as loose fill in residential attics and walls, an inappropriate use for perlite because of its dustiness. These applications also contribute to acoustical insulation of buildings.

Vermiculite is used in building boards of various types. Fine-sized, untreated vermiculite concentrates are used in fire-resistant plasterboard (Tomandl 2002). As heat from a dwelling fire increases, the vermiculite particles expand, compensating for the shrinkage of the gypsum matrix and maintaining the structural integrity of the board. Pressed vermiculite board could be used as a replacement for gypsum plasterboard in many applications. An important market for vermiculite is in sprayable fireproofing for structural steel members. Another use is in intumescent coatings: when heated, the material expands, forming a low-density thermal barrier. Vermiculite is used in refractory brick, castables, ramming mixes, and other articles for service temperatures up to 1,250°C. Vermiculite is used in portland cement and gypsum plasters, enhancing both thermal and acoustical insulating properties. It also is used in acoustical panels and ceiling tiles, but its dark color is a limiting factor in this market.

Since most end uses of vermiculite are associated with construction and industrial uses, the consumption of vermiculite in the United States generally tracked the national economy until the Libby, Montana, mine closure in the early 1990s eliminated the only major U.S. source of coarse-sized concentrates. Typical current market prices for U.S. vermiculite concentrates range from \$60 to \$170/t, depending on size and grade. Imported vermiculite concentrates range from \$127 to \$240/t, f.o.b. (free on board) Gulf Coast ports (Moeller 2004). Current trends in the vermiculite industry are new products and their applications. By mid-2004, there were 23 pending U.S. patent applications dealing directly with vermiculite.

Lightweight Aggregate Insulations

Lightweight concretes are widely used for their contribution to the thermal and acoustical insulation of a structure. Their low density derives from lightweight aggregates used in the formulation. Several categories of lightweight aggregates are used in insulation products. Lightweight aggregates by their nature also enhance the insulating

and fire resistance of a structure when incorporated in concrete products. The air voids in a typical lightweight aggregate act as an insulator. Generally speaking, the lighter the weight, the better insulating and fire-resistant properties (refer to the Lightweight Aggregates chapter in this book). As with perlite and vermiculite, clays, shale, and slate are heated until they bloat. Of the four main categories of lightweight aggregates, three are used in insulation. ASTM compiled specifications for using various lightweight aggregate materials, and these standards should be consulted as required (ASTM 2004e).

- **Natural lightweight aggregates:** These aggregates are prepared by crushing and sizing pumice, scoria, tuff, breccia, volcanic cinders, and other natural materials.
- **Manufactured structural lightweight aggregates:** These are prepared by pyroprocessing shale, clay, or slate in rotary kilns or on traveling-grate sintering machines. A porous but relatively impermeable texture makes these materials not only lightweight but also both thermal and acoustic insulators; makes them desirable for bulk use in floor and roof fill; and gives them an added advantage in saving weight in concrete. Insulating concrete (nonload bearing), weighing as little as 15 lb/ft³, can be made with these aggregates. Fire resistance is enhanced by the low probability of physical breakdown at temperatures below the melting point of the aggregates, by their low shrinkage characteristics, and by their minimum thermal expansion.
- **Manufactured insulating ultralightweight aggregates:** These are prepared by pyroprocessing ground vermiculite and perlite to achieve expansion. Very little use is made of the raw material in its unexpanded form. The most used ultralightweight materials are vermiculite and perlite, but less than 25% is used as construction aggregate. In recent years, significant price increases for expanded perlite and exfoliated vermiculite gave them a large market share in terms of value (approximately 32% in 2002), despite contributing only about 5% of the tonnage.

Foamed Insulation

Foam insulation products tend to be more expensive than other more common types of insulation but are desirable when there are space limitations. Foam insulation can provide up to three times more resistance to heat flow per unit thickness than other types of insulation, and can more effectively control air infiltration if properly installed. Three common varieties are foamed glass, foamed metals, and cementitious foam.

Foamed glass insulation is used for pipes and vessels and also in walls and roofs. Service temperatures for some of these products are as high as 538°C. Foamed glass forms when powdered glass and a blowing agent are heated to form a plastic mass. Gas expansion from the blowing agent forms a closed-cell structure. Foamed metal insulation forms when aluminum and zinc are heated with blowing agents and is similar to foamed glass. Foamed aluminum is very stiff at a very low weight. In addition, it is fireproof, completely recyclable, and very effective in terms of acoustical absorption, electromagnetic shielding, and structural damping (Alulight International GmbH 2004). Cementitious foam, also called foamed portland cement, for mixes when aluminum powder and flake are added to concrete and react with the high pH matrix to form hydrogen gas, resulting in bubbles or cells in the material. It is pumped into closed cavities. The initial consistency of the foam is similar to shaving cream and after curing is similar to a thick pudding. It is easily damaged by water, but is nontoxic and flame resistant.

Other Insulation Materials

Many insulating products contain industrial minerals as a relatively minor constituent or ancillary use; these products have insulating properties as a secondary attribute of their overall performance, or that represent a relatively small market or market segment.

Refractory or Ceramic Fibers

A wide variety of these materials are being produced, including those made from kaolin–aluminum, silica, zirconia, lanthanum chromite, and others. One rather exotic use is in ablative materials that operate in extremely high temperature environments such as spacecraft heat shields. They act as heat sinks, and heat dissipation is accomplished by mass removal. Refractory fibers are used as reinforcement in some of these products. Other uses are in the reinforcement of various resin systems. These materials have found a number of new applications over the past decade. Ceramic fibers are used as high-temperature loose fill in expansion joint construction, furnace walls, and packing around hard refractory furnace components. Older blends were typically kaolin based, but alumina–silica–zirconia and alumina–silica–chromia blends are gaining in popularity.

Asbestos

For health and environmental reasons, asbestos usage for insulation in the United States essentially is nonexistent; in some countries, however, asbestos fiber is still used as reinforcement in calcium silicate insulation. In such products as insulating board, a sandwich construction of two sheets of asbestos cement with a core of insulating material is produced for both interior and exterior use (ASTM 2004f). Asbestos is no longer mined in the United States. Most imports are from Canada. U.S. consumption declined from 6,850 t in 2002 to 4,650 t in 2003 (Virta 2003b). For more detailed information, refer to the Asbestos and Asbestos Substitutes chapters in this volume.

Ceiling Tile

The production of acoustic ceiling tile is mentioned here as an example of an insulation product that consumes large quantities of industrial minerals and rocks in the United States. Currently, the most common composition is spun mineral wool bonded with starch. Another typical composition is 15% clay, 55% mineral wool, 15% perlite, and 15% starch.

Concrete Block Insulation

Concrete block insulation comes in several varieties. In one, the cores of concrete masonry units are filled with insulation, whether poured in, blown in, or foamed in, except for those cells requiring structural steel reinforcing and concrete infill. In some applications, expanded polystyrene is mixed with portland cement, sand, and chemical additives, and polystyrene inserts are placed in the block cores to increase the unit thermal resistance. Hollow-core units made with a mix of concrete and wood chips are also available. They are installed by stacking the units without using mortar (dry stacking). Structural stability comes from the concrete fill and appropriate reinforcing rods throughout for structural walls.

Solid, precast, autoclaved concrete masonry units, commonly used in European construction since the late 1940s but recently available in the United States, have 10 times the insulating value of conventional concrete and are easily sawn, nailed, and shaped with ordinary tools. This type of concrete uses fly ash instead of high-silica sand as its distinguishing component.

Industry Trends

In the past, innovations in the insulation industry tended to focus on improving energy efficiency; in the last decade, however, research focused on health issues. Today a significant portion of industry promotional materials pertains to such topics as airborne dust, free respirable silica, and other health considerations.

Glass fiber and other fibrous mineral insulation materials are of particular interest because of the link between asbestos and cancer. In October 2002, the International Agency for Research on Cancer removed glass, rock, and slag wool fibers from its list of substances possibly carcinogenic to humans (NAIMA 2004b).

Because the fundamental purpose of the mineral insulation is energy conservation and efficiency, these topics remain a key component in insulation industry research. Industry trade groups, most notably NAIMA, work closely with building code officials around the country through the National Association of State Energy Officials to ensure that local, state, and federal regulations are in step with economical and realistic expectations for manufacturers. At the international scale, the focus has shifted from energy conservation to climate change. NAIMA, along with insulation industry trade groups from Europe, Australia, North America, and Asia, issued the 1997 Lisbon Declaration to the United Nations International Framework Convention on Climate Change. The Lisbon Declaration concurs with findings that space heating and cooling of buildings in the developed world is the major contributor to CO₂ emissions and hence greenhouse gases, and that the best method to reduce energy use is to use adequate thermal insulation (NAIMA 2004c). The declaration projects decreases in CO₂ emissions that would result from increased use of building insulation. In the environmentally sensitive sociopolitical climate of the last two decades, the use of industrial minerals in insulation materials is a good example of how mining provides a clear benefit to the environment.

Insulation is one of the few items in new or retrofit residential construction that can be shown to have a finite pay back period, actually saving money for the homeowner. As energy costs inevitably increase over the long term, insulation usage should increase based solely on economics.

The producers of most mineral insulation materials must address the fact that their manufacturing processes are energy intensive. To remain competitive with other insulation materials, these producers should conduct ongoing research to reduce the energy required in these processes, lest the very factors that encourage the increased use of insulation prohibitively increase their production costs.

The use of mineral and mineral-containing insulation will depend on the development and marketing of cost-effective products of high quality while stressing permanence, ease of installation, safety, and performance over competitive products.

Pozzolans and Supplementary Cementitious Materials

Gretchen K. Hoffman

INTRODUCTION

Pozzolans and supplementary cementitious materials (SCMs), either natural or artificial, are often used as a cement replacement or as an enhancement in concrete. Physical and chemical properties of a material determine their pozzolanic or cementitious properties. Table 1 lists the selected characteristics for the major pozzolans and SCMs. Pozzolans react with the calcium hydroxide liberated as concrete hardens, forming compounds with cementitious properties (American Geological Institute 1997). The pozzolanic and cementitious properties along with other characteristics make these materials attractive partial substitutes for portland cement in concrete applications or interground with portland cement clinker to create blended cements. Pozzolans can counteract adverse effects of undesirable aggregates used in concrete and help to create a concrete highly resistant to penetration and corrosion.

For centuries, many of the natural pozzolans have been used in concrete or cement. With increasing fuel costs and environmental concerns over the carbon dioxide (CO₂) emissions associated with the production of portland cement clinker, several pozzolanic by-products of industrial processes are gaining acceptance as admixtures to concrete products. Table 2 lists the major pozzolans and SCMs with production, consumption, and price, where available.

CLASSIFICATION

Pozzolans are siliceous or siliceous and aluminous materials that alone possess little or no cementitious value, but will, in a finely divided form and in the presence of water, chemically react with calcium hydroxide, such as found in cement at ordinary temperatures, to form compounds possessing hydraulic cementitious properties. SCMs are finely divided and noncrystalline or poorly crystalline materials similar to pozzolans that possess latent cementing properties that are activated in the presence of portland cement and water (Malhotra and Mehta 1996). Pozzolans and SCMs are mineral admixtures when added to concrete or blended cements. (For a complete discussion of cement, refer to the Cement and Cement Raw Materials chapter.)

Pozzolans

Pozzolans fall into two categories, either natural or artificial, depending on their provenance. Natural pozzolans are either raw or calcined natural materials—such as volcanic ash, opaline chert, tuff, some shale, and some diatomaceous earth—that have pozzolanic properties (American Concrete Institute 2000). The amount of

amorphous or unstructured material often determines the reactivity of the natural pozzolans. There are three categories of natural pozzolans: (1) volcanic ash, called tuff when indurated, in which the amorphous constituent is a glass produced by rapid cooling of magma; (2) those derived from rocks or earth in which the silica is mainly opal, and diatomaceous earth; and (3) some clays and shales. Volcanic glass has a disordered structure because of the relatively quick cooling time and tends to have a porous texture created by escaping gases. Hydrothermally altered volcanic glass can become zeolitic, and when finely ground, zeolitic tuffs become reactive with lime. Deposits of trachyte tuff from a volcanic eruption near the town of Pozzuoli (Italy) are the source of the term *pozzolan*. Romans used this material with lime to form cement for many of their large building projects. Today, volcanic tuffs and pumice are still used as pozzolans throughout the world and are often referred to as *pozzolana* in the literature.

Moler is a Tertiary-age deposit of diatomaceous earth with significant amounts of clay. These deposits are on the island west of Limfjord, Denmark. Diatomaceous earth is amorphous hydrated silica derived from skeletal remains of diatoms, which are tiny aquatic plants. High-purity diatomaceous earth deposits are pozzolanic, but often they contain large amounts of clays. Depending on the clay content of the deposit, calcination or grinding may be necessary for use as a pozzolan (Flechsigg 1990). Found in France, gaize is a soft, porous, highly siliceous sedimentary rock consisting mainly of opal. Before gaize can be used as a pozzolan, it is calcined at 900°C (American Concrete Institute 2000). Gaize and moler are two examples of natural pozzolans used for their pozzolanic properties. A typical use of moler and gaize is in cement subject to seawater attack.

Although clay and shale are naturally occurring, calcination enhances their pozzolanic characteristics. Calcining is necessary to destroy existing crystal structure and to form an amorphous or disordered aluminosilicate structure. As an example, metakaolin, derived from high-purity kaolin that undergoes low-temperature calcination and grinding to a fine particle size, is a highly reactive product having excellent pozzolanic properties. Not all clays and shales, however, are suitable as pozzolans, even when calcined.

Artificial Pozzolans

Artificial pozzolans used today are mostly from by-product materials. Silica fume is a by-product of the reduction of high-purity quartz with coal in electric arc furnaces in the production

Table 1. Physical and chemical properties of pozzolans and SCMs

Properties	Silica Fume	Ground, Granulated Blast Furnace Slag (GGBFS)	Fly Ash (Class C and Class F)	Calcined Clay, Shale	Diatomite	Rice Hull Ash
Physical	Very fine, tiny spheres (0.1 μm), high surface area—acts as filler	Angular, ground to <45 μm	Fine-grained, spherical, <45 μm	<45 μm rough texture because of grinding	Very fine-grained (1 μm). Porous skeletal remains of single-cell plants	Highly cellular, creating large surface area, >45 μm
Chemical	Amorphous silica	Silicate glass, high in calcium	Aluminosilicate	Aluminosilicate glass; may contain quartz, feldspar, mica	Amorphous silica	Pure silica, noncrystalline

of ferrosilicon alloys and silicon metal. The silicon dioxide (SiO_2) that vaporizes during this process condenses to very fine (0.1- μm diameter) noncrystalline spheres (Malhotra and Mehta 1996). Use of these pozzolanic spheres in blended cement or as a mineral admixture produces a high-strength concrete. Rice hull (or husk) ash, when burned in the production of electricity or milling, produces a high-silica ash. This ash has potential as a pozzolanic admixture in concrete.

Fly ash is a by-product of burning finely ground coal either for industrial application or in the production of electricity. The largest producers of fly ash are electricity-generating stations. The amount of fly ash available is greater than for any of the other by-product materials used in cement or concrete. The composition of fly ash is dependent on the composition of the coal feed and the efficiency of the combustion process. Most fly ash particles are spherical and glassy, and possess pozzolanic properties.

Supplementary Cementitious Materials

SCMs include ground, granulated blast furnace slag (GGBFS) and high-calcium fly ash. Blast furnace slag, a by-product of pig-iron production, when rapidly cooled yields a granulated product that is high in calcium content (35%–40%; Malhotra and Mehta 1996). GGBFS mixed with portland cement has hydraulic properties, creating cement that will harden under water.

Other Considerations

With the exception of silica fume, natural pozzolans and industrial by-products generally cost less than portland cement. The cost savings and beneficial properties of pozzolans and SCMs have increased the use of these products. Most natural rock material used as pozzolans undergo some processing, either grinding or calcination, to improve their reactivity. The percentage of amorphous

Table 3. Natural and artificial pozzolans and SCMs classified by reactivity

Degree of Reactivity	Material
Cementitious and pozzolanic	GGBFS (cementitious) High-calcium fly ash (cementitious and pozzolanic)
Highly active pozzolans	Silica fume Rice hull (or husk) ash from electrical generation
Normal pozzolans	Low-calcium fly ash Natural pozzolans—clay, shale, diatomaceous earth, opaline cherts
Weak to very weak pozzolans	Slowly cooled blast furnace slag Bottom ash Boiler slag Field burnt rice hull ash

Adapted from Malhotra and Mehta 1996.

material in the pozzolan often determines the reactivity of a natural pozzolan. Many of the by-products of manufacturing or electrical generation have acquired pozzolanic or cementitious characteristics during these mechanized processes, and for a few, grinding enhances these properties. The degree of pozzolanic reactivity can vary depending on the method of processing. Rice hulls burned in a furnace reach higher temperatures than those burned in the rice fields and yield a more reactive product. The quality of the original feed, or the combustion and cooling method, can also determine the pozzolanic or cementitious properties (Table 3).

NATURAL POZZOLANS

Industry Structure

Cement companies or businesses specializing in mineral admixtures mine, process, and market natural pozzolans. Depending on the raw material, processing may include grinding, drying, purifying, and calcining. Many of the rocks or minerals used for their pozzolanic properties also have other uses such as lightweight aggregate, soil amendments, filters, or fillers. The product sold as a pozzolan can be a minor fraction of the total end use. In the United States, using natural pozzolans is economic when locally available for bulk concrete construction or in the manufacturing of concrete products. The use of natural pozzolans is more widespread in Europe and Asia than in the United States (American Concrete Institute 2000); the four largest producers of natural pozzolans are Italy, Chile, Greece, and Cameroon (Table 4). Home construction techniques in Europe use less gypsum sheetrock and more stone and concrete than in North America. Prefabricated lightweight concrete walls using pumice as a cement admixture are shipped to the construction site. Pumice as a lightweight pozzolan works well for the European style of construction (Bolen 2003).

Raw Materials and Processing

Natural pozzolans such as calcined siliceous clay and shale, diatomaceous earth or diatomite, and volcanic tuff can be used either as a mineral admixture in concrete or interground with clinker to create blended cements. Most of these raw materials have a variety of applications. The respective commodity chapters in this volume provide more detail on the mining and processing of these materials. Clay, shale, volcanic tuffs or pumicite, and diatomite are commonly quarried with rippers, dozers, and front-end loaders, and then transported to a processing plant. Most of the pumicite mined in the United States comes from western states, including Arizona, California, Idaho, Kansas, Nevada, New Mexico, and Oregon (Bolen 2004). California and Nevada have large diatomite deposits. One location in Nevada is a combination of diatomaceous earth and a diatomic pumicite. The diatomite or diatomaceous earth is processed near the mine site because of the expense of transporting a raw material with high water content. This raw material goes through a series of crushing, drying, and comminution steps. Calcining in a rotary kiln and classifying by particle size with heated air are common processes used to produce a pozzolanic material from diatomite (Dolley 2002).

Water processing of kaolin removes impurities to lighten color and control particle size. Calcining the purified material at 600° to 900°C results in dehydroxylation and a disordered and essentially amorphous state. The product is then pulverized to 1–2- μ m diameter creating a highly reactive pozzolanic product called metakaolin. The use of metakaolin as a mineral admixture has been growing since the mid-1980s (American Concrete Institute 2000). Heating other siliceous clays and shales at 700°–800°C makes them reactive by destroying the crystalline structure of the clays and other minerals in shales. Heating increases the pozzolanic reactivity of zeolites as well (Virta 2002).

Specifications

The American Society for Testing and Materials (ASTM) C311-02 (2003a) specifies the methods for testing raw or calcined natural pozzolans and fly ash for use in portland cement concrete. ASTM C618-03 (2003b) outlines the specifications for use in concrete of natural pozzolans and fly ash, dividing these into Class N for natural pozzolans and Class C and F for fly ash. Comparing the requirements for natural pozzolans to the fly ash classifications,

Table 4. World production of pozzolan in 2003

Country	Commodity	Production, kt
Algeria	Pozzolan	400.0

* Estimated.

† Total is rounded; may not add to totals shown. Total is taken directly from Table 4 of Bolen 2003.

there are few differences between low-calcium fly ash (Class F) and natural pozzolans (Class N). The major differences are (1) the maximum loss on ignition (LOI), or amount of unburned carbon, is greater for natural pozzolans; and (2) the maximum water requirement is greater for natural pozzolans (see section on Fly Ash in this chapter for specifications table). ASTM specifications are not the only standards used in the United States or the world. Almost every country has a different set of specifications for pozzolans used in concrete. Within the United States, each state has its own specifications for use of pozzolans in portland cement concrete for road construction.

Finished Product Uses

A major use of natural pozzolans is in mass concrete, such as dams, where there are large pours and the risk of thermal cracking from the heat produced from the chemical reactions during hydration of portland cement minerals. For example, the Los Angeles Aqueduct (rhyolitic pumicite), the Glen Canyon Dam (pumice; Figure 1), and Flaming Gorge Dam were all constructed using natural pozzolans (American Concrete Institute 2000). Adding natural pozzolans slows down the cementation process, reducing the temperature. Many of the natural pozzolans also improve the workability of the concrete pour, which is beneficial in massive concrete structures. Grouts and mortars are another market for natural pozzolans.

Finished Product Marketing

Markets for natural pozzolans are in blended cements, intergrinding the pozzolan with the portland cement clinker, and as a mineral admixture for concrete. Mining a deposit for a particular project that is nearby and closing the pit when the project is completed is a typical strategy for using natural pozzolans. Natural pozzolans that do not require calcining are the most attractive for marketing beyond a local market. Calcined clay and shale tend to be marketed for blended cements and therefore are used directly by the cement companies. Cement companies have a local market area, because the transportation costs are a limiting factor. Companies mining and marketing diatomite and pumicites as pozzolans often sell these materials as mineral admixtures.

ARTIFICIAL POZZOLANS AND SCMS

Industry Structure

Prevalent use of by-products in the cement and concrete industries is a recent development, particularly in the United States. Using by-products reduces the need for portland cement and uses a product created from expending energy to create another product or electricity. When the by-products are not used, they must be disposed of, which has environmental implications as well. Market barriers for many of these by-products include the wide variety of state regulations regarding their use. If a marketer is transporting the material from one state to another, problems can arise because of the lack of standardization of regulations.

For pozzolanic or cementitious materials such as GGBFS, silica fume, and fly ash, the companies producing the iron or energy generally contract with a mineral admixture marketer or slag processor to handle their by-products. Trade associations such as the Slag Cement Association, the Silica Fume Association, and the American Coal Ash Association (ACAA) represent marketers of these products. These associations promote the product by providing information and technical reports to the buyers and marketers. A discussion for each of the major by-products being used today as a pozzolan or SCM follows. Included is a brief discussion of rice hull ash, although it is not marketed to any extent in the United States.

Silica Fume

Silica fume is a by-product of producing silicon metal or ferrosilicon alloys by reduction of high-purity quartz with coal or coke and wood chips in an electric arc furnace (Figure 2). The silica fume is condensed from gases escaping from the furnace. During the production of silicon metals and alloys, baghouse filters collect the silica fume from the furnace gases. The gas has a very high content of amorphous SiO_2 . Depending on the process, silica fume is 94%–98% SiO_2 from silicon production and 85%–90% SiO_2 from ferrosilicon production (Harben 2002). Silica fume is a very fine, gray powder consisting of glassy spherical particles in the size range of 0.1–0.2 μm with surface areas of 20–23 m^2/g . As a comparison, fly ash is typically less than 45 μm in diameter. The chemical composition, size, and surface area of these particles create a

† A measure of the reactivity (not compressive strength) of given silica fume with a given cement and may vary with the source of both silica fume and cement.

very reactive pozzolanic material. The limited availability of silica fume increases the cost of the finished concrete when added to portland cement, limiting its use to projects where cost is not a primary consideration and the improved performance of silica fume, such as high compressive strength and increased resistance to sulfate attack, are required in the concrete application.

Specifications. ASTM C1240-03 (2003c) outlines the standards for silica fume as a mineral admixture. Table 5 lists the chemical and physical requirements for silica fume. A minimum 85% SiO_2 is required with a maximum of 6% LOI. Physical requirements are concerned with the size and strength when added to mortar. The ASTM requirements also include optional physical requirements for air-entrained concrete, reactivity with alkalis, and sulfate resistance expansion.

Silica fume is the one mineral admixture not considered a lower-cost partial replacement for portland cement in concrete; the cost of silica fume is equal to or greater than portland cement. Using silica fume for its high reactivity creates a high-compressive-strength product that is very durable and can reduce the amount of reinforcing steel required in concrete applications.

Finished Product Uses and Marketing. Concrete admixture suppliers market silica fume. Silica fume in the United States comes from a few producers; the Silica Fume Association lists five member producers. Silica fume products include a fine powder (Figure 3), a densified form, a slurry for mix with water, or a pelletized form for intergrinding with portland cement. The as-produced fine powder is difficult to handle and is generally used in bagged products such as grouts or repair mortars (Silica Fume Association 2004). Densified silica fume is in an agglomerated form created by aerating the as-produced material and creating a net electrostatic charge between the particles. Bulk tankers can transport densified silica fume to concrete batch plants. Unless densified, silica fume is difficult to intermix to form blended cement or to use with portland cement to make concrete, because it tends to float on the surface of the mixture (H.G. van Oss, personal communication). Bulk tankers transport silica fume slurry to storage tanks at construction sites. Often another level of regional supplier repackages the material for the end user in their area. Silica fume is a value-added product in the United States for making high-compressive-strength concrete used in high-rise buildings, parking structures, bridge decks, and girders. In Canada and Europe, silica fume is more often interground with portland cement to create blended cements with high compressive strength, and the cost of the material is much less in this form (Kuennen 1996). Other uses of silica fume include shotcrete mixtures, grouts, concrete blocks, and bricks.

Ground, Granulated Blast Furnace Slag

The iron-making process creates slag during a high-temperature reaction with carbon-reducing agents and fluxes. The impurities of the iron oxide ores and fluxing agents combine to form a liquid silicate melt, called slag, that floats on top of the liquid crude iron. The slag is removed or tapped from the blast furnaces separately. There are several methods of cooling the slag, but quickly quenching the slag in water creates sand-sized particles of glass, granulated blast furnace slag (GBFS; Figure 4), and grinding of this granulated slag increases the surface area and the reactivity of the GGBFS product.

Raw Materials and Processing. The amount of slag produced from a blast furnace is dependent on the chemistry of the raw material, and the grade of the iron ore is the major factor. Ore feed of 60%–66% grade iron in a blast furnace will yield about 0.25 to 0.3 t of blast furnace slag per ton of crude iron produced (van Oss 2003b). Lower grades of ore will yield greater amounts of slag. Blast furnace slags are typically composed of SiO_2 (33%–36%), CaO (calcium oxide, 37%–40%), Al_2O_3 (aluminum oxide, 7%–9%), Fe_2O_3 (iron oxide, 1%–10%), and MgO (periclase 10%–11%). Of the by-products, the chemical composition of slag is closest to that of portland cement; however, slag has a higher silica and lower calcium content (Lohtia and Joshi 1995).

The quenching or cooling process for the slag determines whether the material will be reactive. To form GBFS, the slag is removed from the furnace and rapidly quenched with water in a granulator. The result is glassy granules (Figure 5) that are then dried and ground or interground with portland cement to create blended cement, or the GGBFS is marketed as a mineral admixture for concrete. GGBFS is a hydraulic cement admixture that works with portland cement to create high-strength concrete (Slag Cement Association 2003). Quickly cooled slag using water or steam to

* Slag activity is evaluated by determining the compressive strength of both portland cement mortars and corresponding mortars made with the same mass of 50–50 combinations of slag and portland cement. Slag activity index is the strength activity index (SAI) determination of slag.

† NV = no value given.

form pelletized slag can be interground with portland cement but is often used as a lightweight aggregate.

Specifications. ASTM C989-99 (2003d) classifies GGBFS into three grades based on the slag activity index. This index measures the compressive strength of the mortar prepared in accordance with test method ASTM C109 (2003e). Test mortars containing an equal weight of blast furnace slag to portland cement are compared to standard portland cement mortars. The slag activity index is measured after the mortar has set 7 days and again at 28 days. Measurements are taken on the average of five consecutive samples and individual samples (Table 6). Slag activity index grades are based on minimum percentages; most GGBFS marketed in the United States is 120 grade that has a 95% minimum slag activity index for 7 days and 115% for 28 days. ASTM C595-03 (2003f) states the specifications for using GGBFS in blended hydraulic cement.

Finished Product Uses. Iron-producing companies contract with a processing business to handle the slag. The processor crushes or grinds the slag to meet market specifications, using screens and magnetic separators to recover any metal. GGBFS is a value-added product selling for about \$60/t that can be shipped greater distances. GGBFS can replace from 25% to 50% of portland cement in concrete (Slag Cement Association 2002) and is used in manufactured products such as block, segmental retaining wall units, and pavers. Mixed with hydrated lime, GGBFS can be used in flowable backfills. Specialized concretes can use a combination of GGBFS, fly ash, and silica fume. GGBFS is valued as an admixture in cement for its light color, resulting in a very light colored concrete. Adding GGBFS to a cement mixture gives the concrete greater resistance to sulfate and alkali-silica attack, increased workability while pouring concrete, and durability of the finished product.

Finished Product Marketing. GGBFS production and sales are limited to the eastern United States, near iron and steel manu-

Figure 6. Secondary electron image of fly ash with glass spheres and masses. End product from Salt River Minerals Group, Cholla Generating Station, Arizona. Field of view = 42 μ m.

facturers or near ports where they can receive imported material to grind and market. More than a dozen grinding plants are operating, and the number of blast furnaces in the United States is on the decline. Using existing slag piles, however, is an economical way to remove these piles from the landscape if the material meets specifications (van Oss 2004). If weathered, the slag may not be acceptable for use as a mineral admixture to concrete but can be used as a fine-grained aggregate in cement.

Fly Ash

Fly ash is the major coal combustion by-product of electrical generation from coal-burning power plants. The amount of coal combustion by-product produced at each power plant varies, depending on the type of burners and precipitators, and the percentage of ash in the coal source. The ratio of fly ash to bottom ash produced by coal combustion depends on the type of burner and the type of boiler. Electrical or mechanical precipitators collect fly ash from the flue-gas stream coming from the combustion chamber. This material is glassy, predominantly spherical, and less than 45 μ m in size (Figure 6).

Raw Materials and Processing. Ash in coal consists of minerals and rock particles deposited in the peat swamp or introduced authigenically during the coalification process. Most (95%) of the mineral matter present is clay, pyrite, and calcite. Clay minerals constitute from 60% to 80% of the total mineral content of coal. The types of clay minerals depend on the chemical conditions of the depositional environment. Clays can be detrital in origin or be secondary precipitates from aqueous solutions. Kaolinite is the dominant clay mineral in coals developed in freshwater environments. Illite is dominant in coals overlying marine sediments, developing in moderately alkaline environments. Clays may be finely dispersed in the coal or concentrated in layers, such as tonsteins developed from volcanic ash layers. The mining process also introduces minerals by mining small partings within a seam or from roof or floor material. This dilution adds to the total content of noncombustible material in the coal that ultimately becomes part of the ash by-product.

Coal for electricity generation is finely crushed, typically in ball or roll mills, and air-fed into a 1,037°–1,482°C combustion chamber where the carbon immediately ignites. During coal combustion, the volatile matter vaporizes and carbon burns to heat the

boiler tubes. The inorganic material such as clays, quartz, and feldspar becomes molten and remains in the combustion chamber as slag on the boiler tubes, is carried away by the flue-gas stream as fly ash, or falls through to the bottom of the boiler as bottom ash. The molten material solidifies in the flue-gas stream leaving the combustion chamber, giving approximately 60% of the fly ash particles a spherical shape.

Air pollution control devices, commonly electrostatic precipitators (ESPs), collect the coarse fly ash (>44 μm) first. The finer material is collected later along the air-stream path. ESPs have an overall efficiency of 99%+ (Helmuth 1987). Mechanical precipitators are typically baghouses, cyclones, or venturi scrubbers. Baghouses use fabric filter-tubes or envelopes for capturing fly ash from the flue gas. Baghouses are very efficient for all size ranges (0–44 μm), with an overall efficiency of 99%+ (Helmuth 1987). Several hoppers collect the fly ash particles by size along the length of the ESPs. The captured fly ash can be sent through an air classifier system to ensure consistent grain size.

Depending on the sulfur content of the coal, flue-gas desulfurization (FGD) is necessary to remove sulfur dioxide (SO_2) to meet the 1990 Clean Air Act Amendment standards. Dry scrubbers inject a very fine mist of lime into the unfiltered exhaust gas. The small amount of water used for injection evaporates in the hot exhaust, leaving calcium sulfate (CaSO_4), which is removed with the fly ash. Dry scrubbing creates a fly ash high in sulfur trioxide (SO_3) that is not marketable for most fly ash applications and is disposed of in ponds. Wet scrubbers spray the filtered exhaust gas with a solution of lime, limestone, quicklime, or soda ash as a reactant with SO_2 . In the wet scrubber process, the fly ash is captured before the lime solution is added; therefore it has the potential for being marketed as a pozzolan. Saleable fly ash is loaded into pneumatic containers, either truck or rail, and the remaining fly ash goes to disposal ponds.

Specifications. ASTM C 618-03 (2003b) defines fly ash as finely divided residue that results from the combustion of ground or powdered coal and is transported by flue gases. This definition does not include residue from burning municipal garbage or other refuse with coal, injection of lime directly into the boiler for sulfur removal, or “incinerator ash,” the result of burning industrial or municipal garbage in incinerators.

ASTM C311-02 (2003a) includes chemical analyses and physical methods for testing fly ash used as a mineral admixture in portland cement concrete, and ASTM C618-03 (2003b) outlines the physical and chemical requirements (Table 7). ASTM C618-03 has optional requirements that apply to air entrainment, effectiveness of alkali silica reaction, and sulfate resistance. For use in concrete, state departments of transportation, the Bureau of Reclamation, and the Army Corps of Engineers may have further requirements; Canada and Europe have other standards for fly ash.

In the United States, ASTM C618-03 (2003b) classifies fly ash into two categories (Class C and F) as an artificial pozzolan for use as a mineral admixture in portland cement concrete and Class N for all natural pozzolans (Table 7). Class C normally results from burning sub-bituminous coal or lignite and Class F from burning bituminous coals; however, there are exceptions to this generalization. As an example, lignite and sub-bituminous coal can produce either a Class F or a Class C fly ash. The type of fly ash depends on the depositional environment of the peat swamps from which the coal developed. Classes C and F fly ash differ significantly based on total $\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$ content; Class F has a minimum of 70% and Class C has a minimum of 50%. Fly ash not fitting within these two classes may be well suited for other applications such as soil and waste stabilization but cannot be used in concrete or port-

Table 7. Summary of chemical and physical requirements for fly ash and natural pozzolans defined in ASTM C618-03

	Class N	Class F	Class C
Chemical Requirements			
($\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$), minimum %	70.0	70.0	50.0
SO_3 , maximum %	4.0	5.0	5.0
Moisture content, maximum %	3.0	3.0	3.0
LOI, maximum %	10.0	6.0	6.0
Optional chemical requirements:			
Available alkalis, as Na_2O , maximum %	1.5	1.5	1.5
Physical Requirements			
Fineness: Amount retained when wet-sieved on 45- μm (325) sieve, maximum %	34	34	34
SAI: [*]			
With portland cement at 7 days, minimum, % of control	75	75	75
With portland cement at 28 days, minimum % of control	77	75	75
Water requirement, maximum % of control	115	105	105
Soundness: Autoclave expansion or contraction, maximum %	0.8	0.8	0.8
Uniformity: [†]			
Density, maximum variation from average %	5	5	5
Percent retained on 325 sieve, maximum variation, percentage points from average	5	5	5

^{*} The SAI comes from a control mixture of portland cement mortar and a test mixture of portland cement and test sample in accordance with ASTM C311-02 (2003a). SAI with portland cement is a measure of reactivity with a given cement and can vary as to the source of both the fly ash or natural pozzolan and the cement.

[†] The density and fineness of individual samples must not vary from the average established by the 10 preceding tests, or by all preceding tests if the number is less than 10.

land cement. The intent of these minimum requirements is to ensure that sufficient potentially reactive material is present.

Class F fly ash with less than 10% CaO is considered low calcium and is not self-hardening but exhibits pozzolanic properties. Often this type contains >3% LOI. Quartz, mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$), and hematite are major crystalline phases identified in North American Class F fly ash (Lohtia and Joshi 1995).

Class C fly ash containing more than 10% CaO is classified as high calcium and is cementitious. Class C fly ash typically is derived from sub-bituminous coal and some North Dakota and Gulf Coast lignite. Commonly, the higher the CaO content, the greater the degree of self-hardening. Class C often has a very low LOI of less than 1%. Crystalline phases of the Class C fly ash often include anhydrite, tricalcium aluminate ($\text{C}_3\text{A} \cdot \text{Al}_2\text{O}_3$ or $3\text{CaO} \cdot \text{Al}_2\text{O}_3$), lime, quartz, MgO , mullite, merwinite ($\text{Ca}_3\text{Mg}(\text{Si}_2\text{O}_8)$), and ferrite (Lohtia and Joshi 1995).

Physical characteristics of fly ash and natural pozzolans include size, morphology, fineness, and specific gravity. Fineness is determined by the percentage of the ash retained on a 45- μm (325-mesh) sieve. ASTM C618-03 (2003b) requires that no more than 34% of the fly ash be retained on a 325-mesh screen. Particle-size distribution can be quite variable, depending on the collection method and size,

and can differ within coal from the same mine. The coarser material tends to be less reactive as a pozzolan.

Specific gravity of fly ash is related to chemical composition, color, and shape of the particles. The inconsistency of coal and its minerals makes this quite variable. Specific gravity is increased by opaque spherical magnetite or hematite particles if they are present in sufficient quantity. These materials, along with unburned carbon (% LOI), affect the color of the fly ash. Greater amounts of quartz and mulite decrease the specific gravity. Grinding fly ash may release some volatiles trapped inside the spheres, increasing the specific gravity. Fly ash with a large fraction of low-density particles is more reactive than fly ash with higher density particles, which have iron impurities. Pozzolanic reactivity depends on the amount of low-specific-gravity glass present.

Finished Product Uses. Concrete is a major use of fly ash.

Class F fly ash is used to prevent alkali-silica reaction (ASR) in concrete and is preferred in many southwestern states where the aggregate tends to have reactive material. Light-colored concrete is desirable in some markets, particularly California. A low percentage of LOI results in a light-colored fly ash. LOI percentage can also be a factor in using fly ash in air-entrainment admixtures to counteract freeze-thaw cracking. The type and amount of unburned carbon material can be detrimental to these admixtures. Adding fly ash to a concrete mixture at 15%–25% by weight is common practice. Fly ash works as a fine-grained aggregate in concrete. Processing coal fly ash into pellets through a sintering process allows some systems to use any of the unburned carbon remaining in the fly ash for heat generation.

Fly ash, particularly high-calcium fly ash, combined with lime improves soils for roadway construction. Fly ash can be mixed with recycled pavement to create a new base course, reducing the need for additional aggregate. Roller-compacted concrete (RCC), a very stiff concrete rolled out with asphalt paving equipment, requires large amounts of fine aggregate that can be satisfied with fly ash. Fly ash's pozzolanic properties increase the strength of RCC, lowering the cost. Because RCC is often used in large structures such as dams, lowering the heat of hydration by adding fly ash is very important to minimize cracking. The use of fly ash for these large pours has greatly diminished the demand for Type IV portland cement.

Backfill is low-strength concrete used for infilling trenches. For this use, fly ash is mixed with water and small amounts of sand and portland cement, if necessary. Using Class C fly ash may require less portland cement to form a competent backfill. Fly ash backfill is gaining popularity because it can be poured in place and is less time-consuming than conventional backfilling with compacted soil (Bryggman and Nallick 1993).

Finished Product Marketing. Marketing of fly ash is similar to that of most industrial minerals; quality, consistency, and class of fly ash are very important in determining usage and market area. FGD gypsum contamination by the type of scrubber system installed at a power plant restricts a significant amount of fly ash from use. LOI content can limit usage because unburned carbons are detrimental to concrete or color characteristics. Transportation infrastructure is important, and pneumatic or bottom-dump truck transport is preferred except when large quantities can be shipped by rail and sold to distant markets. Storage facilities at different locations in the market area increase sales but are economically feasible only if the quality of the product is in demand. Fly ash can behave like a specialty mineral in that if the fly ash is of superior quality, distance from market is less of a factor.

Most electrical utilities contract with ash marketers to handle and sell their fly ash as a pozzolanic admixture if it is suitable for concrete. There are more than 40 commercial ash-marketing firms

throughout the United States. Most utilities also employ an ash market specialist to monitor ash quality, use, or disposal and to interface with the ash marketers under contract with the utility (U.S. Department of Transportation 2004). A few utilities have dedicated in-house ash-marketing programs. Ash marketers supply the product to concrete or cement marketers in bulk. Many ash marketers are divisions of concrete companies. In Europe and Asia, fly ash is more often blended in to portland cements; in the United States, fly ash typically is sold as an admixture to the concrete (Table 2).

Ash marketers have load-out facilities and testing facilities at the generating station. They sample and test the fly ash coming from each unit to ensure consistency of the % LOI, fineness, and color (brightness) of the product. Some marketers also air-classify the fly ash they receive from the power plants to maintain consistency of particle size in their product. Marketers also maintain storage facilities in their market areas to absorb excess fly ash production and to maintain a steady flow of material to their customers on short notice. In the United States, fly ash production is greater during certain months of the year when the electricity usage is high, such as summer months in the south and winter months in the north. These times may not coincide with the peak usage times of fly ash, so if the fly ash is highly marketable, storage units are feasible.

Use-Specific Transportation. Concrete, concrete products, and grout are the principal products using fly ash (ACAA 2004a). Fly ash, like many of the other mineral admixtures to concrete, is shipped in pneumatic tanks, bottom-dump trucks, or pneumatic railcars. Many fly ash marketers use trucks as their main mode of transportation if the plant is close to their markets, or if they do not have rail load-out facilities. Where the marketer does not sell large enough quantities of fly ash, rail transport may not be economically feasible. If sales are significant, fly ash is stored dry in silos in population centers to provide an on-demand source of material.

Although today's fly ash marketers analyze the fly ash coming from the collectors on a regular basis to keep their product consistent and maintain quality, this was not always the case, and some concrete producers are still skeptical about using fly ash in their product. Ensuring the quality of fly ash is critical to the growth of the industry, especially in portland cement application (Schwartz 2003). Environmental concerns about concentrations of trace elements in the ash and the possible leaching of these elements also act as market barriers. These concerns are more of an issue in other uses of fly ash, such as structural fill, than in concrete where the fly ash is locked into the concrete matrix. Many of the trace elements have very low solubility in the ash (glass) matrix (D. Pflughoeft-Hassett, personal communication). Using fly ash in cementitious material can reduce the solubility of potentially toxic elements by both chemical and physical mechanisms and can prevent them from leaching into groundwater (Bryggman and Nallick 1993).

Rice Hull Ash

Rice is a primary staple crop in the world, and rice milling produces more than 100 Mt of hulls annually (King 2000). The common practice of burning rice hulls in the field creates a pollution problem. The combustion of hulls to produce energy or burning hulls to complete the milling process creates ash. Collecting and grinding this ash creates a product similar to silica fume. The cost of installing an electric power plant in the United States using rice hulls as fuel is about \$1 million/MW of electric power capacity and requires 1.5–2 t of hulls per MW-hr. In California, 20–25 MWe facilities use rice hulls as a fuel source in the milling process (TropRice 2003). California and Louisiana have rice hull power plants near rice-producing areas. Rice hull ash has the greatest

Table 8. Effects of pozzolans and SCMs on the performance of concrete

Property	Silica Fume	GGBFS	Fly Ash (Class C and Class F)	Calcined Clay, Shale	Diatomite	Rice Hull Ash
Water demand	Depends on mixture	Decreases	Generally decreases; with higher % LOI and coarse (>45 µm) particles, increases	Increases	Decreases because of microporosity	Increases
Workability	Decreases, becomes sticky	Improves	Improves	Improves	Unknown	Improves
Flow of pour	Decreases	Increases	Increases	Unknown	Unknown	Unknown
Compressive strength	High compressive strength attained in same time as portland cement	Lower during first 3–7 days. By 28 days, meets or exceeds strength of portland cement.	Increases slower than normal; with time (+60 days), exceeds strength of portland cement.	Increases with time, slower than portland cement	Increases with time, slower than portland cement	Moderately high, greater than portland cement
Durability	Increases	Increases	Increases	Increases	Increases	Increases
Heat of hydration	Accelerates temperature rise in first 72 hours	Lower	Lower, except in high-calcium fly ash	Lower	Lower	Same as portland cement
Air-entrainment agent	Increases demand	Increase demand	Higher % LOI, greater demand	Unknown	Unknown	Increases demand
ASR resistance	Increases	Increases	Increases	Increases	Increases	Increases
Sulfate resistance	Increases because of refined pore structure	Increases	Increases with Class F fly ash	Increases	Increases	Increases
Bleeding of hydrated lime, Ca(OH) ₂	Lower than normal; increases potential for cracking	Generally lower	Generally lower	Lower than portland cement	Lower than portland cement	Negligible difference

Adapted from Malhotra and Mehta 1996; Lohtia and Joshi 1995.

potential in major rice-producing countries such as China and India. The market for rice hull ash has not developed in the United States to the point of having specific marketers of the product.

ADVANTAGES OF POZZOLANS AND SCMS

Mineral admixtures have many advantages in portland cement applications where they can improve the properties of concrete. Their pozzolanic or cementitious nature adds a component by replacing part of the portland cement in concrete, in general reducing cost. Offsetting the use of portland cement by using mineral admixtures can save energy and lower CO₂ emissions from cement plants.

The chemical and physical properties of the different mineral admixtures (Table 1) when added to concrete determine what properties of the concrete are enhanced. Table 8 lists the effects of these admixtures on the performance and other attributes of concrete. Characteristics of concrete influenced by adding pozzolans or SCMs are discussed in the following paragraphs.

The very fine particle size of many of the mineral admixtures can be advantageous when the aggregate is deficient in sand-sized material (Lohtia and Joshi 1995). The admixtures act as filler and are part of the cement paste, reducing the total surface area to be coated with cementitious material. Adding fine (1–20 µm), spherical particles such as fly ash can also refine the pore structure in the concrete, which reduces the amount of water needed to produce a concrete of certain consistency. Conversely, the angular shape and microporosity of some natural pozzolans increase the water demand in the concrete mixture. The percentage of LOI can also affect the amount of water needed to create the needed consistency of the concrete.

Workability is the homogeneity and ease with which concrete can be mixed, transported, compacted, and finished (Ramachandran

and Feldman 1995). The spherical shape of the fly ash, in particular, acts like ball bearings and increases workability of the concrete, decreasing the need for aggregate fines. Calcined shale and clay also improve the workability of a concrete pour; silica fume, however, actually decreases workability because of its highly reactive nature.

Strength and durability of concrete are improved by the fine-grained nature of mineral admixtures, which decreases the porosity of the concrete (Lohtia and Joshi 1995). Formation of cementitious compounds by pozzolanic reaction causes pore refinement and reduces microcracking in the transition zone between the concrete and aggregate. This significantly improves the strength and durability of the concrete. Because of retarded heat of hydration, adding fly ash, GGBFS, or natural pozzolan to concrete lowers the early strength. Strength increases over time and eventually meets, and can exceed, the strength of concrete made with portland cement alone. Silica fume is highly reactive, and concrete made with silica fume attains high compressive strength in the same time as portland cement concrete and exceeds the norm in 3 days (Lohtia and Joshi 1995).

Heat of hydration is an exothermic reaction during hydration of portland cement. Pozzolanic reactions occur after cement hydration begins when Ca(OH)₂ becomes available. Replacing a portion of the portland cement with fly ash or most natural pozzolans retards rate of hydration and manifests pozzolanic reactions late in the aging process of the concrete. As a rule of thumb, the percent reduction in heat liberated at 7–28 days is about one half the percentage of mineral admixture substitution for portland cement. Conversely, silica fume is highly reactive and accelerates the temperature rise in the first 72 hours (Lohtia and Joshi 1995). Heat of hydration is slower for GGBFS than for portland cement, and the hydration products tend to be more gel-like than portland cement, filling voids and increasing the ultimate strength of the concrete. Reduced heat of hydration is particularly important in

massive structures where the temperature increase becomes significant and can lead to cracking because of thermal stresses induced in hardened portions of the concrete mass.

Using air-entrainment admixtures (AEAs) in cement or concrete enhances the freeze-thaw resistance by increasing the void content of the concrete. The addition of most mineral admixtures increases the demand for AEA. Class C fly ash (high calcium) generally requires less AEA than Class F. The key factor is the % LOI, which appears to increase the need for AEA. This increased demand can influence the amount of water used in the mixture, depending on the type and amount of admixture added.

The presence of reactive material in the aggregate, such as opal, chalcedony, siliceous shale, and schist, causes ASRs in concrete. ASR occurs when silicate minerals react with alkali metal ions (as Na_2O and K_2O) in portland cement paste, forming a gel. With moisture, the gel can swell and expand and crack the concrete around the individual aggregate particles, causing pop-outs. Most mineral admixtures are effective in controlling ASRs. The available alkali in the mix is reduced by the amount of admixture added, as long as this material itself does not contain soluble alkalis. The size of the particles (0–45 μm) improves the packing of cementitious materials and reduces the permeability of the concrete because of the pozzolanic action. This reduces the ion migration and available external moisture in the concrete, increasing the resistance to ASR. The smaller particles of the pozzolans are preferentially attacked by alkaline solutions (sacrificial silica), forming a calcium-silicate hydrate (C-S-H) that is more stable than the silica gel and protects the aggregate from ASR attack. Some high-calcium fly ash (Class C) containing large amounts of soluble alkali sulfates increases the alkali-silica reactivity. For this reason, Class F fly ash is preferred to counteract ASR. Natural pozzolans, silica fume, and GGBFS are also effective in dealing with alkali-silica reactivity.

Concrete in certain applications must resist chemical attack by seawater, sulfate-bearing groundwater, or leaching by acidic waters. Sulfates such as gypsum react with hydration products of the tricalcium aluminate (C_3A) phase of portland cement to form ettringite. This formation of ettringite can cause swelling and internal cracking, which ultimately weakens the concrete. Adding mineral admixtures improves the resistance of the concrete to these chemical attacks through lowering the amount of C_3A by reducing the percentage of portland cement. The pozzolanic reactions of the mineral admixtures help decrease the permeability of the concrete, making it harder for harmful chemicals to penetrate the concrete.

GOVERNMENT, ENVIRONMENT, AND HEALTH CONSIDERATIONS

The biggest challenges for natural pozzolans are environmental concerns of CO_2 reduction and conservation of natural resources. Mining the natural pozzolans also requires energy, and often the raw materials then undergo drying, grinding, and calcining, which uses significant energy and produces some CO_2 . Using industrial by-products recycles materials and reduces the depletion of natural resources. Although these by-products were created through industrial processes requiring energy that creates CO_2 emissions, little or no additional energy is needed to create a usable product, making by-products very attractive to the portland cement industries, competing directly with many of the natural pozzolans. As an example, CO_2 emission savings for fly ash are almost a 1:1 exchange by weight (B. Kepford, personal communication).

Challenges lie ahead in the utilization of fly ash. The 1990 Clean Air Act Amendments requires power plants to reduce nitrogen oxide (NO_x) emissions. Lowering NO_x emissions generally restricts oxygen during the combustion process, resulting in more

unburned carbon (% LOI) in the fly ash. Unless the fly ash goes through a washing process to remove the carbon, the fly ash is unsuitable for use in concrete, its largest market. Some NO_x removal systems leave residual ammonia on the fly ash. Depending on the type of coal, the amount of ammonia adsorbed can differ. Although the ammonia does not have a detrimental effect on the performance of fly ash in concrete, ammonia fumes liberated in the concrete mix can be objectionable under certain working conditions (EPA 2003b). There is some concern of health problems related to the direct inhalation of fly ash (EPRI 1998). Because fly ash particles are spherical, they may be less likely to lodge in lung tissue than angular particles from other sources. Very small particles (<10 μm), however, can go deep into the lungs. Coal ash does contain small amounts of other materials, and there is the potential for irritation and inflammation of lung tissue. Personnel working in the ash collection process, as ash haulers and silo operators, have the greatest potential for inhaling this material. An Electric Power Research Institute technical report (1993) concluded that routine operating activities did not produce hazardous exposure.

On the positive side, the use of fly ash reduces greenhouse gases; for every ton of coal ash used, there is a 0.89-t reduction (this can vary) of greenhouse gas (Schwartz 2003) created in the production of portland cement. Using fly ash in concrete or in blended cement reduces land disposal requirements and reduces the use of raw materials in creating portland cement clinker.

Silica fume is a very fine-grained material and should be treated as any other respirable dust. Although silica fume is amorphous silica, some small amounts of crystalline silica are present below measurable limits. The presence of any quartz requires warnings on the material data safety sheets for silica fume.

TRENDS AND OPPORTUNITIES

Portland cement and concrete are major growth industries, and in the past 10 years, more portland cement manufacturers have realized the benefits of using pozzolans and SCMs in their product. Pozzolans and SCMs add durability to the concrete, extending the life cycle of a project. Another industry trend is the increased use of by-products over calcined clay and shale. As part of implementing sustainable development, conservation of natural resources has added to the desirability of using SCMs derived from industrial by-products. Production of blended cement containing natural pozzolans decreased from 192,000 t in 2001 to 187,000 t in 2002 in the United States. Fly ash is the leading by-product used in part because of the large volume produced—more than any of the other by-products—and its lower cost. Silica fume is a high-value product and only has certain applications. GGBFS use is limited in the United States by the decline in production from blast furnaces; sales of GGBFS have grown, however, and the need for GGBFS is being met by importing material. Fly ash use in clinker and blended cement has increased over the past several years in the United States, and clinker's predominant use is as a partial substitute for portland cement. The U.S. cement industry's 2003 consumption of fly ash for clinker was 2,250 kt and 39 kt for blended cement (van Oss 2003a). The concrete industry consumes a significantly larger volume of fly ash (11.1 Mt) as a substitute for portland cement in concrete (ACAA 2004b). Primary consumption of GGBFS is for blended cement, which has decreased from 369 kt to 333 kt for 2002 and 2003, respectively (van Oss 2003a). van Oss hypothesizes that this decrease is because of "lower sales volumes of slag-rich blends of concrete" or decreased use of slag as a grinding aid to make Type 1 portland cement.

The demand for cement worldwide is projected to rise 4.1% through 2006, with China as the largest market. Other developing

countries in Asia/Pacific, Latin America, and Eastern Europe are expected to have greater demands for cement as well (*Mining Engineering* 2002). Along with this growth, the demand for blended cements and pozzolanic materials will increase. Blended cements are attractive because of the potential to lower carbon emissions by partial replacement of cement clinker with industrial by-products and the superior performance of blended cements in certain applications. Barriers to greater usage of blended cements depend on availability, transportation costs, building code standards, and other legislative requirements (Worrell et al. 2001). Potential for CO₂ reduction varies by country, depending on current use of blended cements and the availability of blended materials. As an example, China's use of coal for power generation and significant iron production make it a candidate for using blended cements. Currently, China uses primarily portland cement. By using blended cements, China could significantly reduce its carbon emissions from clinker production (Worrell et al. 2001).

ACKNOWLEDGMENTS

The author thanks Hendrick van Oss of the U.S. Geological Survey for his thorough review, which made a tremendous difference in the content. George Austin and Jessica Elzea Kogel helped considerably with the organization of this chapter, and Ken Santini supplied significant background material that facilitated the writing. The Slag Cement Association, the Silica Fume Association, and Greer Price supplied the author with digital photos. The author greatly appreciates all of these contributions.

Roofing Materials

Daniel N. Leavell

INTRODUCTION

The roofing industry offers many opportunities for industrial minerals and rocks suppliers to develop high-value, year-round markets for their products. This market opportunity is not widely known in the aggregates industry, and few of the manufacturers of roofing materials have a good idea of the alternate materials available near their plants. Materials routinely produced for aggregate may be graded in relatively narrow size ranges, and offered as components for use in a wide variety of composite roofing types.

Many natural and synthetic materials are used as roofing materials around the world. The local choice is based on necessity, custom, available materials, material cost, and the anticipated life of the structure. In underdeveloped areas, low-cost and widely available materials such as brush, thatch, or palm fronds may be used. These may be enhanced with clay, mud, or even bitumen. Such organic materials are not expected to have a long life and must be renewed at regular intervals. The low weight of the roof system, however, allows the homes to be constructed using minimal materials, which keeps costs to a minimum.

With increasing urbanization, a desire for more permanent homes leads to the use of heavier-weight materials. More robust homes are capable of supporting a heavier roof structure, and mined earth materials such as slate or flagstone and tiles made of clay or concrete have commonly been employed. Roofing made of metal, which can range from inexpensive corrugated sheets to much more costly, coated modular steel systems, is also very popular around the world. Increasingly, composite roofing materials fabricated of natural and synthetic materials are used because of their lower cost, ease of transport, and greater flexibility of application.

This summary of roofing materials focuses on the opportunities for supplying industrial minerals and rocks to composite roofing manufacturers in North America (as this is where the author has gained his experience). Many of the ideas in this chapter, however, are applicable to markets worldwide.

ASPHALT SHINGLES

Asphalt shingles are the most popular and least costly form of roofing in use today in the United States. In residential construction, asphalt shingles account for nearly 85% of all roofing. Shingles are made to a high standard of quality and are available in a wide variety of styles and weights. Even the least robust shingles are

designed for a life of at least 20 years. Heavyweight, high-end shingles now offer warranties of 40 to 50 years.

Although called *asphalt* shingles, this roofing material is a true composite with asphalt representing an important, although minor, component. By weight, shingles are more than 80% mineral and rock, and shingle manufacturers provide a broad target market for industrial minerals producers. Asphalt roofing shingles are a heavyweight product, so roofing plants are located throughout the United States to avoid high shipping costs. Mineral and rock supply to these individual plants is largely a regional business as well, for the same reason. Previous editions of this volume have focused only on roofing granule production and supply, but many more opportunities for supply to asphalt roofing manufacturers exist, as described in this chapter.

As manufactured in the United States, asphalt roofing shingles are produced in several broad categories. The largest percentage of production is of 3-tab shingles, which are considered the standard of low-cost dimensional roofing. An increasing percentage of production is of what are called architectural or laminated shingles. These new-style shingles offer a dimensional look and are typically of a heavier weight. In addition, many roofing plants still manufacture rolled asphalt roofing and smaller interlocking shingles for use in high-wind areas.

All of these products are manufactured in the same way, using the same basic ingredients. The differences are in the amounts of the ingredients and in the manner in which the shingles are cut at the end of the production line. Asphalt shingles are made in a continuous sheet, up to 60 in. wide. The sheet moves through the machine at speeds as high as 700 fpm, and in just seconds all the materials of the shingle must be applied to build the composite structure while the asphalt is still hot. Granules must be pressed into the asphalt-saturated mat before cooling begins. The sheet is then cooled rapidly and delivered to the cutting machine, which cuts the sheet into standard-size tab shingles or builds a laminated structure for the architectural-style shingles.

Figure 1 shows typical examples of both 3-tab and laminated shingles. At the heart of the shingle is a fiber mat, most commonly made of nonwoven fiberglass, although some shingles are still made with a paper mat. The mat is saturated with mineral-filled asphalt coating, which is applied to both the top and bottom surfaces of the mat. The greatest performance-enhancing differences

Figure 1. Three-tab and laminated shingle construction

in all the shingles made are in the weight of the mat and in the thickness of the applied asphalt layers. While the asphalt-saturated mat is still very hot, granular rock materials are placed first on the topside of the sheet and later on the backside of the sheet. The granular materials consist of rock granules coated with colored ceramic (prime granules), rock, or slag granules with a similar gradation (headlap granules), and finer silt-sized granules deposited on the backside (backdust).

Top-surface granules give the shingle substantial weight, and prime granules also provide protection for the asphalt, which is the waterproof layer of the composite shingle. Because sunlight's UV rays degrade asphalt, prime granules must be effectively opaque to UV light to shield the asphalt. Today prime granules are colored by a ceramic coating, and nearly a dozen colors are available. These are used either as single colors like white or black, or more commonly as blends of colors, placed on the shingle surface in complex patterns for visual effect. Headlap granules serve little purpose other than to balance the sheet, although they do give weight and substance to the finished shingle.

Because the requirements of roofing plants in the United States and Canada, each requiring significant year-round supply, huge potential opportunities exist for supplying all of these graded rock materials. The greatest opportunity by weight is in supply of fine-grind mineral filler. Individual plants require a minimum of 100,000 t of filler per year. Granules, both prime and headlap, are also used in high volume by each plant, and represent the greatest expense of manufacturing shingles, particularly the ceramic-coated prime granules. Backdust material supply is a smaller opportunity, but can be a lucrative use for mineral fines from aggregate production. Each of these materials is considered in detail in the sections that follow.

TOP-SURFACE GRANULES

The coarse, graded aggregate that is applied to the top surface of asphalt shingles serves several purposes. Colored prime granules provide the distinctive colors and patterns of the finished roof and protect the asphalt layer from rapid degradation by UV radiation. Headlap granules may provide some distinctive appearance in 3-tab shingles, but in laminated shingles these granules exist only to add weight to the shingle and coat the asphalt of the top half of each shingle. Headlap granules offer UV protection only in 3-tab shingles. In all other types of shingles, headlap granules are not exposed on the roof. The growing popularity of laminated shingles has

resulted in many new opportunities for granule supply to individual roofing plants.

Prime and headlap granules share some characteristics but have significant differences in performance requirements. Although in some plants, prime and headlap granules may come from the same quarry, in most cases the two types of granules are likely to be quite different materials. Ideally both granule types should share the same gradation—a rather narrow size range (ASTM [American Society for Testing and Materials] #11)—which resembles coarse sand (12 × 40 mesh, U.S. Sieve Series). For production reasons it is important that both prime and headlap granules have a similar bulk density and roughly the same granule shape. Shingles are made in wide sheets, and these qualities ensure that the weight of applied granules will be equal across the sheet. Both types of granules should be durable and capable of bulk handling without breaking down into smaller pieces. The granules should also be able to withstand multiple freeze-thaw cycles without decrepitation to give the roof a long life.

Prime Granules

Previous editions of this chapter in *Industrial Minerals and Rocks* (Kalyoncu 1994) focused on the potential business opportunity for colored prime granule production. Although the potential profit margin of prime granule production is great, the technical experience and capital expense required to compete with existing granule suppliers is also very high. The days of supplying prime granules to only one or two roofing plants are gone, with most shingle manufacturers now supplying their products nationally from many regional plants. Their desire for uniform products across their manufacturing line precludes entry by startup granule suppliers. Today, most prime granules are produced by only two suppliers, 3M Corporation and ISP Specialty Minerals. Both companies produce uniform colors of ceramically coated granules at multiple plants strategically located across the country.

Although a number of rock types are used as the base rock for coated granules, all are either igneous or metamorphic. The base rock for prime granule production should be inherently opaque to UV transmission and uniform in color. Fine-grained rocks are preferred, and the best granules tend to be made from rocks that, when crushed, have a shape that is not dominated by a strong mineral cleavage.

The shape and natural gradation of granules made from any two rocks will be different and dependent on the type of crushing equipment employed, as well as on the nature of the rock. In practice, the best granules have been made from meta-volcanic rocks, with fine grain size and a relatively light color. These rocks crush uniformly to an approximately cubical shape and can be color-coated thoroughly and consistently. Crushing and screening roofing granules requires considerable experience and care. The desired size distribution (ASTM #11) is narrow, and production of excess fines is undesirable. Waste from the screenings is nearly 50%, and existing granule producers struggle to find suitable uses for the fines.

Color coatings are applied to the base granules in large batches, and the pigmented clay-rich coatings are fired in rotary kilns. Producing consistently coated granules is difficult, and process and batch control are critical for color consistency. Existing prime granule manufacturers employ elaborate storage and shipping techniques to ensure that shingle plants receive consistent supplies of individual colors. The coating must be durable in material handling, as well as stable in application to the shingle.

In humid climates, a small percentage (10% or less) of the prime granules may be replaced by special algae-resistant (AR) granules. These AR granules are made with a layer of copper oxide

beneath the colored ceramic coating. The copper leaches slowly from the coating over the life of the shingle, acting as a biocide to inhibit the growth of algae on the shingles.

Headlap Granules

Traditionally, shingle manufacturers have favored dark-colored granules, with high UV opacity, for shingle headlap. The materials used include both graded rock aggregate and various industrial by-products. Supply has been dominated by specialty companies marketing industrial slags, such as those produced as a by-product of coal combustion in certain old-style power plants. These coal slag supplies have become increasingly scarce because modern coal-fired power plants do not produce a coarse glassy slag. Consequently, the slags have become increasingly costly as many old waste areas have become depleted. At the same time, a shift in shingle style toward laminated shingles without exposed headlap areas has opened an excellent market niche for traditional rock aggregate producers.

Headlap granules are produced to the same physical and gradation standards as prime granules but can be made from many different crushed rocks, and even from coarse sand and gravel deposits. Opacity to UV transmission is not a concern with laminated shingles, and even some carbonate rocks can yield good headlap granules. Consistency of bulk density and granule gradation is of greatest concern to the shingle maker, because the weight of granules per unit area, as applied to the shingle sheet, must be held nearly constant for reliable shingle machine operation.

Granules are typically produced to the rather narrow size range of the ASTM #11 gradation standard (12 × 40 mesh, U.S. Sieve Series). Tolerance for fines in the product is low. Production of such a fines-free sand product from crushed rock can result in significant waste material. A beneficial use for the fines from granule production can mean the difference between a successful operation and a failure. Fines may be added back into a more traditional manufactured sand product or they may be further screened to yield backdusting granules, as described in the following section. Even without a beneficial use of the fines from headlap production, the relatively high cost of headlap can result in a profitable specialty product for a traditional rock aggregate quarry. To compete in the headlap market, a supplier must be able to provide granules at a delivered cost of \$35 to \$45 per ton. Individual roofing plants use upward of 50,000 t of headlap per year, and the largest plants in the United States require 3 to 4 times this quantity.

BACKDUST GRANULES

In asphalt shingles, backdust is used primarily as a parting agent on the bottom or backside of the shingle. Backdust typically consists of fine, sand-sized rock granules that are liberally applied to the hot asphalt coating just prior to the cooling section of the shingle machine. The backdust works to isolate the hot asphalt from the cooling and guide rolls, and also prevents shingles from sticking together when packaged.

Backdust materials are widely varied, both in size range and material properties—ranging from finely crushed talc to crushed carbonate, igneous and metamorphic rock fines, and even crushed glass and slag. Naturally sorted sedimentary silica sand has been the backdust of choice for many years because of its easy handling, ready availability, and low cost. Asphalt shingles have a wide tolerance for these diverse materials, although each shingle process has been optimized for the material in use.

Some backdust materials perform by coating or blanketing the sheet. This is typical with talc or some of the crushed carbonate backdusts, which have a higher percentage of fines. Other backdusts

Table 1. Mohs mineral hardness scale*

Mohs Number	Mineral Name	Common Tool Hardness
1	Talc	
2	Gypsum	Fingernail: 2.5
3	Calcite	Penny: 3.5
4	Fluorite	
5	Apatite	Glass plate: 5.0–5.5
6	Orthoclase	Knife: 5.5–6.0
7	Quartz	Steel file: 6.5–7.0
8	Topaz	
9	Corundum	
10	Diamond	

* Softest = 1, hardest = 10

perform by holding the shingle away from the adjacent sheet or roll. Median grain size of these coarser granular materials will be critical as shingle manufacturers alter the amount of backcoating on the shingle. Thicker backcoating requires a coarser backdust to isolate the sheet, particularly from the cooling section.

Although the shingle process has a wide tolerance for material differences, as with filler, consistency of the backdust is very important to system performance. Suppliers must strive to produce consistently sized materials with consistent bulk density and flowability. This is relatively simple with sand products that are not crushed but produced from loose sediment or disaggregated sedimentary rock. Often these products will not vary much because of the nature of the mined materials. The supplier must tightly control crushed products, such as talc, carbonate, slag or glass, to ensure consistent properties.

One of the high-maintenance areas of shingle manufacture is in the shingle cutting machine. Here the sheet is cut into individual shingles and unique shingle patterns are cut and laminations are assembled. Backdust properties seem to have a considerable effect on the life of materials used in cutting knives in the shingle machines. The difference in the Mohs hardness (Table 1) of the minerals used for shingle backdusts, relative to the hardness of the steel used for the cutting knives, appears to be a major controlling factor. Many shingle lines use silica sand as their backdust, and this material is considerably more resistant to wear than steel. Simply changing to backdust material made from a softer mineral has been shown to result in significantly less wear and lower operating costs. Talc and carbonate backdusts are considerably softer than steel, but even backdusts made from slag or glass offer a hardness advantage over silica sand.

The gradation of backdust sand employed is highly varied throughout the roofing industry. The granule gradation is chosen for its performance as applied to the shingle, and individual plants may make several different specification shingles. Typically the gradations have been fine—a relic of the migration away from using talc and the readily available sand supplies of the coastal plains and river systems of the continent. With thin backcoating on lighter weight shingles, fine-size distributions have worked well; however, heavier-weight shingles require thicker backcoating and a consequent shift to coarser gradations to protect the equipment and prevent sticking of the shingles in the package. The sand must be appropriately sized for the process in which it will be used. Shingle manufacturers may use multiple sands to accommodate the needs of a diverse product line.

The most difficult aspect of producing backdust sand from a crushed rock is obtaining a sufficiently fine sand size without

significant fines (less than 5% to 10% –200 mesh). A target gradation is typically 50 × 200 mesh (U.S. Sieve Series). A dedicated process is needed to produce such a restricted size range consistently. Material removed from the crushed rock at the top end of the sand gradation can be made into a shingle headlap. Headlap granules (10 × 40 mesh) have not traditionally been carbonate rock, but with the production of laminated shingles, carbonate headlap is practical. An effective air classification process should be used to control the tail end of the backdust gradation. Excess fines produced by sand gradation can be added to agricultural lime or landscape pellets.

Backdust Materials

Talc

Talc was more widely used in the past but is now used in only a few plants nationwide. Although talc is the most expensive backdust in use today, less material is needed for each shingle because of the platy nature and fine size of the talc dust. Because talc applies to the shingle sparsely, however, the resulting shingles have a lower weight of backdust and require an increased amount of filled coating. This increases the material cost of the shingle. Concerns about the mineralogical association of talc with asbestos also limit talc's desirability. The low Mohs hardness of talc is a plus; the mineral has no impact on the wear of cutting knives.

Carbonate

Carbonate refers to backdust made from crushed limestone, dolomite, and marble, with mineralogy having little, if any, impact on the performance of the backdust. High-quality backdust can be produced from any hard crystalline carbonate rock, such as those produced by aggregate suppliers for construction and road building. Carbonate backdust is made from crushed rock, and because fines must be controlled, it is fairly expensive to make and somewhat difficult for a supplier to control. The material is dusty and may result in backdust transfer issues, both in manufacturing and in later material handling of the shingles. In certain areas of the country where crushed limestone prices are low, there are distinct advantages to using carbonate backdust, and this material can be very effective in a backdust system. Because the Mohs hardness is significantly less than that of steel, the backdust has considerable less wear potential than silica sand, resulting in greatly reduced knife wear.

Silica Sand

A majority of U.S. roofing plants use silica sand as a backdust. The size distribution and mineralogy of this sand is dependent on the source and somewhat varied. All are predominantly silica (quartz) and inherently hard. Typical minor minerals are feldspar and mica. Although most silica-sand backdusts are from naturally graded sedimentary deposits, these backdusts also have the potential to contain fine, respirable, crystalline silica, which has been identified as a carcinogen. Because all of the silica sands were deposited as sediments, they tend to have rounded grains and great flowability.

Slag

Only a few shingle manufacturers use industrial slag backdust (glass from a refractory process) today, although the use of fairly coarse coal slag sand is increasing and shows good potential because of low material costs. A number of existing slag headlap suppliers could potentially supply useful sand-size slag fines.

Glass Sand

Specialized equipment can crush glass sand from postconsumer-waste bottles to subangular particles. Glass sand can be tailored to a useful gradation, and, in application, compares favorably to silica

sand. Because of the lower Mohs hardness of glass (Table 1), manufactured glass sand offers the potential for significantly reduced wear to the cutting knives of shingle machines. As with carbonate sand, fines in the backdust must be minimized. Producing sand backdust from postconsumer glass is a beneficial reuse for glass, particularly the broken tricolored waste that is typically landfilled today. Many glass recyclers that produce cullet have considerable stockpiles of broken tricolor glass too fine for separation. Cullet for remelting must be of a higher quality than that required for shingle backdust.

Backdust Value

The delivered cost of backdust sand ranges from about \$20/t to a high of nearly \$40/t. Talc is an exception and may cost as much as \$85/t. Talc, however, behaves differently in application than other materials, and it goes much further. Typical sand application rates are about 6 to 10 lb/square of shingles, so individual plants will require upward of 15,000 tpy. It is important to understand the price of competing materials in each market because price depends on a available materials and proximity of supply to the end user. Most sand supplies are delivered by truck, with a typical supply of 2 to 3 days on hand at the shingle plant.

MINERAL FILLER

Fillers or extenders have long been used in the fabrication of asphaltic roll roofing and roofing shingles. Initially the motives were probably purely economic, to incorporate a waste material (roofing granule fines) into the asphalt, extending the filled-coating asphalt and thereby reducing the overall cost of saturating asphalt per unit of roofing. Reducing the cost of saturating asphalt is still the primary motivation for the use of fillers, but the addition of filler material enhances certain performance characteristics of a roofing product, altering the rheological properties of the filled coating and enhancing its resistance to weathering by sunlight.

Early shingles used felt or cellulose for the mat of the shingle, and saturating asphalt had to be nearly pure to infiltrate the mat. Too much (or too coarse) filler was unable to be pressed into the mat, and saturation was incomplete. With the introduction of fiberglass mat (more porous but also stronger) in sheet roofing, an increase in filler percentage was possible, allowing for greatly reduced filled-coating costs. Shingles are made today with filled coating that contains as much as 67 to 68 wt % filler.

When roofing was made primarily at the same location as the surfacing granules, there was little incentive to use any filler other than the rock fines that resulted from crushing and grading rock granules. With the proliferation of roofing plants and the recognition by granule makers that they could profit more from selling colored granules from a small number of large plants, roofing plants sprouted closer to the end-user markets, away from most of the raw material suppliers. This opened the door for manufacturers to try alternate filler materials. Fine-grind carbonate rock is the filler of choice today.

Although dolomite has been effectively used as asphalt filler for roofing, today most manufacturers prefer high-calcium limestone (greater than 91 to 92 wt % calcium carbonate [CaCO₃]). High-calcium filler is believed to result in shingles with higher tear strength, although the mechanism underlying this result is not fully understood. Dolomite is a slightly harder mineral than calcite, and it is likely that the higher-strength shingles result from the interaction of slightly softer filler and the fiberglass mat. Regardless of an explanation for the interaction, manufacturers have come to demand high CaCO₃ content, and consistency of filler chemistry, gradation, and moisture is critical for manufacture of consistent shingles.

Many limestone deposits are quite varied in chemistry, requiring selective mining of the higher-grade, calcium-rich layers. Other variables that may negatively affect filler performance include silica (commonly present as minor chert), silicates that may be introduced in to the ground limestone from included soil, and even insoluble organic material in the limestone.

Carbonate fillers are produced from many different rocks, ranging from marl to marble. Few roofing plants share a filler supply, and many rock and crusher combinations are employed effectively throughout the industry. The best fillers in use are those that are produced as a primary product of crushing, rather than as a by-product of some other crushed stone product. Crushing systems work most efficiently when the mill receives a consistent feed supply, and the resultant filler is likely to have a consistent gradation and chemistry. Material quality control requires routine sampling and testing.

No single filler gradation has been established by the industry. Typically, filler is made to a standard of 60% to 65% passing a 200-mesh screen; however, many roofing plants use finer filler (up to 80% passing 200). Each rock and crusher combination will yield a slightly different size distribution in the ground rock. Typically, roofing plants have learned to work with the material available at a low price and within a reasonable distance of their plant. Filled-coating systems have been adapted to accommodate the available material. Consistency of the material is probably as critical to maintaining a long-term supply contract as the chemical consistency of the limestone.

In general with finer gradations of filler, more material handling difficulties may be encountered in shipment, transloading, and in-plant handling of the filler. Filler must be transferred from trucks or railcars into plant storage silos, which may hold 300 or more tons. The filler must then transfer freely through a filler heater before being combined with the hot asphalt. If the filler has an abundance of superfine particles, or even excess moisture content, it may not flow well through the system and can cause production problems in the shingle plant.

Today mineral filler is the largest component of roofing shingles (by weight or by volume), and having a timely and efficient transportation system in place is a key part of filler supply. Plants require nearly constant supply to their systems, and the most attractive portion of a supply contract may be on the transportation and delivery side. It is common for plants to require 10 to 15 trucks per day, every day of the year. Delivery of filler by rail, which allows material to be sourced at a greater distance from the plant, still requires 400 or more train cars per year. The price that the rock supplier receives for the material and labor typically reflects only about one half of the delivered cost of the product. Here is the biggest problem with filler supply; roofing plants expect high-quality control and consistent material properties, but they want to have rock-bottom pricing. As the demand for more calcium-rich filler continues, the price of filler should increase because of competing demand for the high-calcium stone in flue-gas desulfurization, animal feeds, and other chemical applications.

SUMMARY AND FUTURE TRENDS IN ROOFING MATERIALS

Specialty roofing, such as clay and concrete tiles, metal, and fiber-reinforced tiles of plastic and cement, are typically high-end products with limited or regional markets; however, the market for these traditional and innovative roofing materials is growing. Also, traditional materials such as slate and wood shingles remain in demand in certain areas of the United States. Because of the high initial cost

of installing these specialty roofing materials, however, the demand for asphalt shingles remains strong. The market for asphalt roofing shingles is expected to grow at an annual rate of 2% to 3% for the next several years. This includes both shingles for new construction and re-roofing of existing homes. The industry has seen much consolidation in the last two decades, and there has been a trend toward national markets and less regional supply of shingles. Manufacturing plants have been increasing their capacity, and suppliers of materials have grown to keep up with demand. Innovation in shingle materials and design, along with a continual desire to reduce material costs, offers excellent opportunities for aggregate suppliers to broaden their product lines to include headlap and backdust surfacing granules. Backdust can also help rock crushers to utilize some of their waste rock fines.

Breaking into the supply chain for asphalt shingle manufacturing can be difficult because the industry is conservative and change can temporarily interrupt a high-speed manufacturing process, adding to short-term costs. But the opportunity for both the supplier and the manufacturer is great. Industrial minerals and rocks suppliers should assess the potential market in their areas and consider whether these narrow-specification products can be made with minimal capital additions to their plants. Next, they should find out what manufacturers are located in the region and explore their current supply situations. Production managers should be consulted to see if they are open to change, and if a new material might help them reduce the cost of production or enhance the performance of the process and product. Some readers of this chapter may, however, be coming from the shingle manufacturing side. Manufacturing managers may not be aware of local and regional industrial minerals supply and should take some time to learn what natural rock materials are available locally. Freight costs can easily be as great as material expenses in granule and filler supply, so innovative supply scenarios can cut material costs significantly.

If industrial minerals and rocks suppliers can identify a cost-effective market for their materials and meet the rigid specifications for consistency and quality control needed for roofing material supply, asphalt shingle supply can provide a stable, year-round outlet for high-value, mined-rock products. Breaking into the market might be difficult, but opportunities for success are great.

Structural Clay Products

Denis A. Brosnan and J. Gregg Borchelt

INTRODUCTION

Structural clay products are semi vitreous clay ceramic, prismatic-shaped units used in masonry construction and pavements. These products are made by forming moist, earthen raw materials into the desired shape, drying to remove free water, and heating or “firing” to temperatures in the “red heat” range (i.e., temperatures greater than 950°C). Exposure to these temperatures partially fuses the mass so that the bricks, when cooled, are composed of residual minerals bonded with a vitreous or glass phase. It is the vitreous nature of structural clay products that produces their well-known strength and durability.

Other types of masonry units are also used. Concrete masonry units consist of aggregates bonded by hydrated calcium silicate cement (portland cement). Calcium silicate (sand lime) bricks, consisting of siliceous aggregates and sand bonded by lime in a hydrothermal (autoclaving) process, are available in many parts of the world. Adobe bricks are unfired earthen units that are sun-dried and used as such; some adobe bricks are made with portland cement or asphalt admixtures to slightly improve their resistance to rain. (The reader is referred to the chapter on adobe and earthen construction in this volume.) None of these units is heated or processed to high temperatures. Concrete masonry units, calcium silicate bricks, and adobe bricks are thereby differentiated from structural clay products by their lack of a vitreous bond.

Structural clay products (hereafter restricted to and called *brick*) have been produced for at least 8,000 years, and fired bricks have been manufactured for at least 3,500 years. Brickmakers in the Roman Empire were particularly proficient in the firing process, and 1,000-year-old Roman buildings still survive in excellent condition. It was the Roman tradition that led to load-bearing design for brick walls in European buildings—with stucco-covered clay structural (or load-bearing) brick predominating in southern Europe.

Clay facing bricks have been used with clay structural bricks in northern Europe after the Roman tradition. The use of facing bricks and structural bricks was the predominant form of construction in North America until World War II. Thereafter, brick became a popular facing material backed by concrete masonry units (i.e., veneer cladding), or brick veneer is used over wood or steel stud walls in residential or commercial construction (Figure 1). Brick veneer is also used over concrete masonry, concrete, or steel stud backing (the last on framed buildings). In veneer applications, the brick serves as an exterior cladding attached to the backing with a

Figure 1. Bricks are used extensively as facing material for buildings

series of steel anchors. Since 1980, clay paving bricks have gained a large market share in North America.

BRICK PRODUCTION IN THE UNITED STATES

Brick production in the United States rose steadily in the late 1990s to a level of more than 9.2 billion standard brick equivalents by 2004. The brick industry uses the term *standard brick equivalent*, or SBE, as a basis for comparison. An SBE has dimensions of $7\frac{5}{8}$ in. (length) \times $2\frac{1}{4}$ in. (height) \times $3\frac{7}{8}$ in. (thickness). It corresponds to a nominal modular size brick.

Brick production roughly follows residential housing starts. Nearly 80% of bricks produced are consumed in the residential market. Since 1992, the average number of bricks consumed per housing start has been relatively constant at about 5,000 bricks.

In 2003 there were 75 businesses operating at 180 locations (with more than 420 individual kilns) to manufacture clay bricks. They employed 14,199 workers with a payroll exceeding \$430 million. Firms with 500 or more employees represented 8% of the brick manufacturers, and these firms operated 52% of all the brick plants. More information is available from the U.S. Census Bureau (<http://www.census.gov>) and the Brick Industry Association (BIA; <http://www.gobrick.com>).

Figure 2. Bricks exhibit ranges in colors and can be blended for an overall visual effect

In the United States, the South Atlantic region (Delaware, Maryland, District of Columbia, Virginia, West Virginia, North Carolina, South Carolina, Georgia, and Florida) predominates in brick production, accounting for 39.0% of the total manufactured while consuming 33.7% of all bricks produced in 2002. The East South-Central region (Kentucky, Tennessee, Alabama, and Mississippi) ranks second in importance in brick manufacturing. This area produced 19.0% of all U.S. brick and consumed 15.5% of the bricks produced. Although virtually all brick manufacturers ship into many states and regions, the geographic distribution varies depending on the size of the producer company. Larger firms are more likely to ship their products throughout the United States, whereas smaller firms tend to ship only to adjacent states or neighboring regions.

The market share for bricks in residential construction in the United States is about 20% for new single-family houses. This share has declined since the early 1970s, but it has held steady since the late 1990s. Bricks are sold directly by producers as well as through brick distributors. Current pricing is available from individual producers.

More than 20 brick sizes are available, with modular brick ($3\frac{5}{8}$ in. wide \times $2\frac{1}{4}$ in. high \times $7\frac{5}{8}$ in. long) accounting for just less than 50% of production. The next most popular size, accounting for 18% of production, is “king size” (3 in. wide \times $2\frac{5}{8}$ in. high \times $9\frac{5}{8}$ in. long). Thousands of uniquely colored and textured bricks are available from producers, allowing consumers to create a unique, personalized appearance for their residences (e.g., Figure 2). The demand for brick is based on the image it creates. Bricks with an antique look have gained in popularity in recent years. Brick remains the preferred facing material on upper end residential structures.

STANDARDS FOR BRICK IN THE UNITED STATES

Brick products must meet standards published by the American Society for Testing and Materials (ASTM, <http://www.astm.org>) if the manufacturer either voluntarily or contractually (in the sale) represents that the product complies with a particular product standard. Several standards relate directly to requirements for bricks:

- ASTM C216, *Standard Specification for Facing Brick (Solid Masonry Units Made from Clay or Shale)*

- ASTM C652, *Standard Specification for Hollow Brick (Hollow Masonry Units Made from Clay or Shale)*
- ASTM C902, *Standard Specification for Pedestrian and Light Traffic Paving Brick*
- ASTM C1272, *Standard Specification for Heavy Vehicular Paving Brick*

ASTM C67, *Standard Test Methods for Sampling and Testing Brick and Structural Clay Tile*, gives testing procedures for brick products. Information on the content of these standards is found in the section titled Key Physical Properties of Brick in this chapter.

ASTM standards for brick are included in building codes adopted by governmental agencies to provide minimum standards for construction. Building codes also provide requirements for masonry construction, and local codes should be consulted for specific requirements.

The *Technical Notes on Brick Construction* series (BIA, various dates) gives design, construction, and maintenance information on brick products.

BRICK MANUFACTURING

Raw Materials

To make brick products, earthen materials obtained by open-pit mining methods are used. These materials must, when processed, contribute plasticity (cohesion) when mixed with water and must exhibit an acceptably broad range of vitrification so that firing may be accomplished in continuous “tunnel” kilns. The plasticity requirement ensures that bricks can be formed and handled for subsequent drying and firing operations.

Raw materials used in brick manufacturing generally are called *clays*, although they may contain only a limited amount of substances considered clay minerals. Clays can vary in chemical composition and mineral origin. Typical raw materials are shale, alluvial clay, and mixtures thereof. Clay minerals usually are members of the kaolin, illite, and smectite mineral groups. Fired brick usually exhibit a chemical analysis of 10% to 20% Al_2O_3 ; 0.5% to 6.0% Fe_2O_3 ; and 50% to 60% SiO_2 . Most of the silica is chemically combined with the residual clay or located in the vitreous phase (i.e., it is not a free or available entity).

The color of fired bricks originates in the intrinsic content of transition metal elements such as iron. Oxidized forms of iron give bricks their typical red color (from hematite, or Fe_2O_3 crystals, held in the vitreous phase). Bricks produced by reduction firing, also called “flashing,” have a characteristic blue-black color from the transformation of hematite into magnetite, or Fe_3O_4 , and the reaction of FeO with silica to form an iron silicate called fayalite (FeSiO_3).

Many brick plants mix clays from different sources to produce unique fired colors. Colorant oxides such as iron oxide and manganese oxide may be added to clays to provide uniform “through body” colors. Many bricks have surface-applied colorants (colorant applied as powdered pigments) or surface-applied slurries of clay and pigments. Glazes containing pigments can be applied to obtain an impervious surface. The surface of bricks can be deformed to provide an antique appearance, and sand can be applied to the surface of the bricks to produce either temporary or permanent textures or colors.

The chapter on clays and shale provides a more detailed discussion of the clay used in brick manufacture.

Clay Processing and Brick Forming

Clay from the mine is crushed and ground to the required particle size. Many plants stockpile or store raw materials to avoid the need to dry the clay during rainy weather. The clay moves through the primary and secondary crushing operations and is screened or “scalped” to about 8 mesh (2.46 mm) and finer sizes.

Forming, Drying, and Firing

Bricks are formed by machines using either extrusion or molding processes. In extrusion, augers push the wet clay mass through an orifice to produce a continuous clay column, which is cut into individual brick units. In molding, a wet clay mass is forced into individual cavities (molds) and subsequently demolded. When producing many molded bricks, sand or water applied to the mold surface prevents the clay from sticking to the wood or metal mold. These bricks are referred to as sand-struck and water-struck brick, respectively. Few manufacturers make traditional hand-molded bricks.

The dry pressing method is used for a minority of clay brick production; the primary method of forming brick is the extrusion method, used for 91.4% of brick shipments in 2002. The machine-molded method is used for 6.8%, and dry pressing accounts for 1.8% of brick production from the reporting companies.

Bricks are dried in continuously fed tunnel dryers, with bricks stacked or loaded on wheeled cars. Kiln cars transport stacked settings of bricks through the kilns. Most bricks are fired in tunnel kilns (Figure 3), where the bricks are exposed to an increasing temperature to a maximum or "soak" temperature condition. More than 90% of the kilns are fired with natural gas. The bricks are then cooled to room temperature for packaging and transport (Figure 4). Waste heat from the cooling section of the tunnel kiln is used in the dryers to maximize thermal efficiency. Some brick plants use periodic kilns: the bricks are loaded in the kiln and remain in a stationary position for the entire firing process. The fired bricks are then packaged "cubed" and strapped for delivery.

Key Physical Properties of Brick

ASTM C216 (for facing brick) and ASTM C652 (for hollow brick) address the following physical properties: compressive strength, boiling water absorption, saturation coefficient, and initial rate of absorption.

Compressive Strength

Compressive strength is the maximum compressive stress the bricks can withstand when loaded on the bed surfaces. Bricks qualifying as Grade SW (severe weathering) must exhibit an average compressive strength of 3,000 lb/in.² (20.7 MPa [or 211 kg/cm²]) for five test specimens, with any individual test result no less than 2,500 lb/in.² (17.2 MPa). Bricks qualifying as Grade MW (moderate weathering) must exhibit an average compressive strength of 2,500 lb/in.² (17.2 MPa) for five test specimens, with any individual test result no less than 2,200 lb/in.² (15.2 MPa).

Bricks usually meet the compressive strength requirement with considerable margin to spare. For example, the average compressive strength of extruded face brick manufactured in the United States exceeds 11,000 lb/in.² (75.6 MPa). Compressive strength is attributed primarily to the quantity of fired bond created in the vitrification process.

Boiling Water Absorption

When bricks are submerged completely under boiling water at atmospheric pressure for 5 hours, they increase in weight (compared to their dry weight) because of water absorption in their pores (small capillaries remaining in the fired product). Boiling water absorption is the percentage increase in weight. For Grade SW bricks, the maximum allowed average boiling water absorption is 17.0% for five test specimens, and any test result on an individual brick specimen must be no greater than 20.0%. For Grade MW brick, the maximum allowed average boiling water absorption is 22.0% for five test specimens, and any test result on an individual brick specimen must be no greater than 25.0%.

Figure 3. Bricks exit a modern tunnel kiln after firing

Figure 4. Many brick plants use robots in manufacturing

Saturation Coefficient

The saturation coefficient is the ratio of cold water absorption (i.e., the weight percent of absorbed water in bricks immersed in water at room temperature for 24 hours) divided by the boiling water absorption. The average saturation coefficient for five test specimens must be no greater than 0.78 for Grade SW brick and 0.88 for Grade MW

brick, with minimum individual values no greater than 0.80 and 0.90, respectively.

The water absorption and the saturation coefficient reflect the pore quantity and the pore structure, respectively, in the brick after firing. These are influential in giving resistance to freezing and thawing of bricks in cold weather climates. If brick walls become partially saturated with water and then freeze, ice will form within the brick's pore structure behind the face of the brick. When the absorbed water expands on freezing, pressure is exerted behind the face of the brick. Part of this pressure is relieved if ice can expand into larger pores; ice trapped in smaller pores (typically those less than about 2 μm), however, may cause cracks to develop.

Repeated freezing and thawing may result in a fatigue-like failure of the brick, causing spalling or the loss of layers of material more or less parallel to the original face of the brick. The tendency for bricks to fail from freeze-thaw is exacerbated by a high degree of water penetration or the lack of protection on horizontal brick surfaces from pooling water, as in parapet walls, on window sills, on chimneys, on garden walls with inadequate water protection on the face of brick against earth fill, on exposed steps, and so forth.

Bricks qualify as Grade SW in two ways even though they may fail to meet the saturation coefficient criterion. Bricks with an average cold water absorption of 8% or less for five specimens fully qualify as Grade SW under an "Alternate." In addition, bricks passing the freezing and thawing test described in ASTM C67 qualify as Grade SW under the Freezing and Thawing Alternate regardless of the water absorption characteristic.

Criteria for the compressive strength, boiling water absorption, and saturation coefficients were established following extensive empirical research to assure consumers that the brick is durable under freeze-thaw conditions. The criteria do not guarantee that freeze-thaw damage will not be seen in bricks, because many other factors ultimately influence resistance to freezing and thawing. It is also important to note that the freezing and thawing qualification for brick is applied at the point of sale. Testing bricks for freezing and thawing is beyond the scope of the standard after the sale of the product, for example, after removing bricks from a wall or after ambient weather storage.

Initial Rate of Absorption

A brick's initial rate of absorption, or IRA, is the weight gained after the dry brick is laid bedface down to a constant immersion depth of $\frac{1}{8}$ in. (3.2 mm) of water for 1 minute. The weight gain is expressed in grams per square inch of surface area and the results are placed on a common basis of grams of water absorption per 30 in.² of surface area (g/30 in.²-min). IRA is not a specified property for bricks by ASTM standards. The IRA ranges from values of less than 1 g/30 in.² to more than 60 g/30 in.².

Research has demonstrated that the IRA of bricks may be matched to mortar type used in masonry construction to provide the maximum possible flexural bond strength and minimal potential for water penetration (leakage) through the wall. The ASTM standards for facing brick, ASTM C216, and hollow brick, ASTM C652, contain advisory notes that bricks with an IRA greater than 30 g/30 in.²-min should be prewet with water to have their IRA reduced before construction (i.e., before laying bricks). Model building codes for masonry also have this requirement. Additional research has further indicated that strong and watertight joints can be obtained for brick of any practical IRA range.

Other Criteria for Brick in ASTM Standards

Specifications for brick in ASTM standards include sections on efflorescence (discussed in the section on Infrequent Problems Seen

with Brick Masonry in this chapter), materials and finish, sizes and tolerances, and coring and frogging (voids within units). Under materials and finish, limits for cracking and chippage are specified, with a specific viewing distance to observe cracks. The standards also give provisions for sampling and testing. Appearance criteria are determined through the definition of types of bricks. Type FBS for facing bricks and Type HBS for hollow bricks are considered the standard for U.S. production. Tighter limits on dimensional tolerances, chippage, and cracks are applied to types FBX and HBX, respectively, than to other types as defined in the ASTM standards. Bricks with appearance requirements more liberal than the FBS or HBS designations are identified as Type FBA for ASTM C216 and Type HBA for ASTM C652.

Quality Control in Brick Manufacturing

Quality control consists of measuring size, measuring physical properties, and judging appearance using methods in the appropriate ASTM standard for the type of product. Brick color typically is judged at brick plants by comparison of daily production with a standard color panel assembly of bricks. Architects may require contractors to assemble a field-acceptance panel at the job site to compare the delivered product to that specified. Judging compliance to color of field acceptance panels should be done in natural light.

Recycling and Reclamation

Brick plants use essentially all the raw materials brought into the plant. Oversize materials in grinding are reprocessed and used. Extrusion scrap (shaved material) is returned to the extrusion machine. Fired brick scrap is used as grog, or it is crushed and sold as landscaping cover material. Waste products from other sources are sometimes added to the brick body to improve the processing of the clay. Sawdust and bottom ash (the latter from coal firing) are frequently used for this purpose.

Clay pits are usually reclaimed for agricultural use or restored and designated as wetlands or wildlife habitats. Open-pit clay mining usually produces a shallow pit, in contrast to the deeper pits from stone quarrying operations.

USES OF BRICK

Factors Affecting the Quality of Brick Masonry Construction

Bricks are rugged and durable products of commerce, and they are one of the components of a building's wall. The total functionality of the wall system is obtained through the responsibilities detailed as follows:

1. The designer of the wall, typically the architect, must provide design details according to recommended practices, including means for supporting the wall, anchoring the wall to the structure, draining the wall system, placing vapor barriers and flashing, and other details as required by building codes. The BIA's *Technical Notes* series contains recommendations for these components. Failure to provide proper design details can result in performance problems for the wall.
2. The masons who construct the brick masonry have many responsibilities at the job site (Figure 5). The masons and their helpers mix mortar materials according to specifications for the job; they inspect bricks on receipt; they build the wall using wall ties, flashing, weep holes, and so forth, as necessary; they blend bricks (colors) during assembly of the wall; and they strike or tool mortar joints. Failure to perform proficiently in any aspect at the job site can result in an inferior quality wall, creating problems for the building owner, which may include a wall that is not aesthetically pleasing.

3. Laborers who clean brick masonry, typically the contractor's workforce, must clean the bricks according to the brick manufacturer's recommendations. Improper cleaning, with acids, for example, can cause efflorescence or metal staining of bricks. Pressure washing, if performed improperly, can damage surface coatings or the brick itself.
4. The brick manufacturer must ensure that bricks meet ASTM specifications as agreed to by the manufacturer and building owner.

Infrequent Problems Seen with Brick Masonry

Water Penetration

Brick veneer walls are technically classified as drainage walls, where water is channeled to the back surface of the veneer. Water that penetrates the veneer flows downward and away from the building through weep holes over flashing at support locations. Water may penetrate the brick units by normal capillary processes. Such penetration results in a short-term increase in relative humidity in the cavity, or void space between the bricks and the sheathing attached to the building frame. Brick cavities are designed to promote air circulation to maintain average humidity at a level compatible with ambient weather conditions.

Most cases of excessive water penetration of the veneer are the result of inadequate filling of head joints (vertical joints) with mortar. Small cracks may develop between the brick and mortar because of a mismatch between brick and mortar properties (e.g., failure to prewet high-IRA brick) or moving the brick after contact with mortar. These conditions may result in water damage to the inner portions of the walls if the air space between the bricks and their backing is not clear, if there is inadequate flashing, or if weep holes are not used in the wall system.

Freezing and Thawing Durability Failures

Loss of portions of the exposed brick surface, commonly called *spalling*, may occur from repeated cycles of freezing and thawing. Such failures usually are found in locations where a high exposure to water occurs—such as in chimneys, window sills, garden walls, steps, or high places on tall buildings. Freezing and thawing durability failures do not necessarily indicate that the bricks lacked sufficient resistance to freezing and thawing as provided under ASTM standards. Lack of proper chimney caps, lack of flashing on parapet walls, allowance of pooling of water, and other design faults may be the underlying causes of these failures. Inadequate expansion allowance in the wall may result in similar spalling.

Efflorescence

Efflorescence is the deposition of water-soluble mineral salt crystals on a brick surface. Although all bricks contain a very small proportion of soluble salts, only a few contain a concentration sufficient to form visible efflorescence. The process of efflorescence is well known. Water penetration begins the process, dissolving soluble material in the brick over time. Through evaporation and drying, the salts are left on the outer surface of the brick. Drying removes the water from the outer surface and the salt is deposited following evaporation.

The efflorescence test described in ASTM standards is not required for bricks to meet the ASTM specification unless requested by the purchaser. This test exposes bricks to water followed by a drying period to show if the brick units develop efflorescence. The test provides a rating of “not effloresced” or “effloresced.”

Efflorescence frequently is associated with water used in the construction of a building, and it is not recurring as the structure ages.

Figure 5. Masons lay brick using age-old techniques.

When recurring efflorescence is observed, it should be removed by cleaning the surface of the bricks by methods recommended by the manufacturer. Chemical cleaners are used only after thorough saturation of the bricks with water and by strictly following directions for use of that cleaner. Lack of adherence to prewetting and other requirements of the cleaning process can cause an efflorescence problem of increasing severity.

Not all efflorescence is caused by salts within the bricks. Efflorescence may be related to the mortar used in masonry construction. The primary efflorescing species in mortar are calcium compounds that dissolve in water during wetting periods and move through the bricks during drying periods. This type of efflorescence may be white. Saturation of a brick wall with muriatic acid (HCl) is a well-known cause of “mortar efflorescence.” Other sources of efflorescence, particularly with brick pavements, are soluble materials in underlayment or substrate materials, impingement of irrigation water sprays, use of deicing salts, and impingement of fertilizer or herbicide products.

Chippage

Chippage is the loss of small pieces from the edges or corners of bricks. Manufacturers have made major advances in packaging in recent years to limit chippage during delivery to the job site. At the job site, masons should discard bricks exhibiting excessive chippage. ASTM standards for bricks, for example, allow 100% of bricks shipped to a job site to contain chippage to a limited extent. Chippage, however, should not detract from the appearance of the wall. After the wall is built, the manufacturer is not responsible for chippage of the brick units.

Face Cracks

Bricks infrequently exhibit minor cracks across their face, and it is known that these do not reduce the performance of a veneer. To evaluate the presence of “significant” face cracks, ASTM specifications for bricks specify a viewing distance where, if face cracks are visible, the crack may detract from the appearance and functionality of the wall.

Color Variation in Bricks and Mortar Discoloration

Because of the natural variation in clay chemistry and the techniques of brick production, bricks exhibit a natural range in shades

and tones of color. It is the job of the mason to follow the brick manufacturer's instructions for blending different colored bricks at the job site to produce a wall of normal color variation. After construction, bricks may be stained by skilled commercial personnel using inorganic pigment solutions; staining is a widely accepted practice to correct color of bricks in a wall. Staining is usually guaranteed for the life of the structure or 100 years.

A number of factors affect the appearance of mortar. Skilled masons know that mortar joints must be finished, or "struck," within a defined time range after assembly of the masonry, or color variation in the joints may result. Mortars colored with inorganic pigments may exhibit color variations if the concentration of colorant varies from batch to batch of mortar mixed at the job site. Improper cleaning can remove portions of the cement paste and alter the resulting color in the mortar joints. Mortar joints can be stained by skilled personnel to correct color variations.

ENVIRONMENTAL CONSIDERATIONS

Brick Manufacturing

Brick manufacturing emits small quantities of pollutant species into the environment, primarily particulate matter consisting of natural clay dust and dilute acids. The dilute acids are hydrogen fluoride, sulfuric acid, and hydrogen chloride, and their concentration is typically far below the threshold for any type of human health effect. Bricks have been manufactured for thousands of years, and brick plant workers exhibit no greater incidence of disease than the general population.

In 2003, brick plants in the United States became regulated under the provisions of the National Emission Standards for Hazardous Air Pollutants (NESHAP) promulgated by the U.S. Environmental Protection Agency. Even before that time, a number of brick plants had air pollution control devices or "scrubbers" installed to limit emissions from their kiln exhaust. These scrubbers remove acid species from the kiln exhaust. With the implementation of the brick NESHAP, many larger brick plants are likely to use scrubbers.

Brick Products

Extensive studies of brick products show that they do not release hazardous species into groundwater during service. Bricks are considered "green" products that support sustainable construction. The latter is attributed to the long life of brick masonry buildings and to the fact that bricks are recyclable and may be used for other purposes. More information is available from the BIA.

FUTURE TRENDS

The brick industry in North America has undergone significant expansion over the last decade; most new plants use automation. One result is greater uniformity in the physical properties of bricks. Increasing cost pressure on fuel prices represents an important challenge to the industry from a manufacturing perspective.

Brick production will continue to shift to thinner bricks with a greater percentage of void area. These thinner, lighter bricks will provide the appearance and performance attributes of standard bricks but offer savings of materials and energy.

In the marketplace, the trend to use bricks in more expensive residences may continue. The brick industry has recently employed extensive advertising to make the consumer more informed of their choices for residential cladding. Use of brick in governmental, business, and industrial buildings is expected to continue despite the recent availability of numerous competitive materials. Using mixtures of cladding materials for decorative purposes may expand. Growth in the use of brick paving is anticipated.

RESOURCES ON BRICK PRODUCTS

The following organizations offer information on brick products, their production, and their use:

- Brick Industry Association, 11490 Commerce Park Drive, Reston, VA 20191; 703-620-0010; <http://www.gobrick.com>.

The mission of the BIA is to promote clay bricks in order to increase its market share and to safeguard the clay brick industry. It accomplishes this by serving the united interests of the brick industry, primarily to promote the sale and use of clay bricks; to be the authority on brick construction; to render technical assistance to designers and others; to provide education and assistance for the brick industry; to further good relations among brick distributors, manufacturers, and suppliers; to monitor and positively influence governmental actions; to assist in the long-term availability of bricklayers; and to provide member services.

Regional brick associations may be available in certain areas, and these are listed on the BIA Web site.

- The National Brick Research Center, 100 Clemson Research Boulevard, Anderson, SC 29625; 864-656-1094; <http://www.brickandtile.org>.

The mission statement of the National Brick Research Center states that the center will advance the technology of clay brick materials and products, augment the education of ceramic and materials engineering students, and educate and serve individuals in the brick industry with a resultant increase and improved use of structural clay building products. The National Brick Research Center is a component of Clemson University, Clemson, South Carolina.

Cosmetics

Peter A. Ciullo

INTRODUCTION

Relatively few minerals are used in cosmetics, and their level of use is generally too low to warrant separate statistical consideration compared to major consuming industries. Sales to the cosmetics industry generally are relegated to the category of “Other.” Although tonnage may be relatively small, their use is nevertheless widespread. Talc, kaolin, calcium carbonate, mica, or smectite clay is used in nearly every type of personal care product intended to make the skin look or feel better. The smectite clays and their organoclay derivatives contribute emulsion stabilization, suspension stabilization, and thickening and binding properties, and are used in most product forms offered by the cosmetics industry. Talc, kaolin, and calcium carbonate are used for their inherent physicochemical properties, mainly in decorative cosmetics, whereas the micas, both muscovite and sericite, are also used for their optical properties. Table 1 summarizes the functions and applications of these minerals.

The most common vehicle in the cosmetics industry is the emulsion, which brings water, oils, fats, waxes, and active ingredients to the skin in an effective, homogeneous form. As creams and lotions, emulsions improve the condition of the skin. Functional additives adapt them for specific uses: UV absorbers in sunscreens, alpha hydroxy acids in keratolytics, melanin inhibitors in skin lighteners, and mild abrasives in exfoliants. Emulsions decorate with the addition of pigments and minerals. Decorative or color cosmetics also are made without water (e.g., face powders and nail lacquers), but seldom without minerals. The most mineral-intensive products, clay masks, are based more on what they remove from the skin—oils and impurities—than what they leave behind.

INDUSTRY STRUCTURE

Although the word *cosmetics* is commonly inferred to mean decorative products such as foundation and nail enamel, this chapter adopts the common industry understanding, which includes skincare, hair care, and personal hygiene products as well. On that basis, the worldwide cosmetics industry can claim sales of \$230.5 billion in 2004, fully half of which is accounted for by only 10 companies (Briney 2005). Although six of these are U.S. corporations, North American sales are 22% of the total, third in line after Western Europe at 31% and Asia/Pacific at 25% (Briney 2005). Multinational producers dominate the global cosmetics industry, but private label companies, producing products for themselves and others under various brand names, are regionally significant. It is also an

Table 1. Minerals in cosmetics: Functions and use

Mineral	Function	Typical Application
Talc	Lubricity, skin adhesion, water resistance	Foundation
	Absorption	Foundation
	Fragrance retention	Foundation, dusting powder
Kaolin	Absorption	Foundation, masks
	Matting	Foundation
Calcium carbonate	Absorption	Foundation, masks
	Matting	Foundation

Mica	Pigmentation	Foundation, lip colorants, nail enamels
Sericite	Lubricity	Foundation
	Sheen	Foundation
Smectite clay	Thickener/stabilizer	Emulsions, liquid foundation, nail enamels (organoclay)
	Absorption	Masks

industry with a relatively low cost of entry. Nearly anyone with a sales pitch can enter the business and succeed depending on their marketing savvy and the value of their products. Two of the largest U.S. cosmetics companies, Avon and Mary Kay, started as “mom and pop” ventures. Today, aspiring cosmetics moguls take advantage of relatively low cost—low risk exposure provided by the Internet and the somewhat more expensive, but potentially more responsive, television infomercials and shopping channels.

EMULSIONS

The primary function of creams and lotions is to make the skin soft and supple. This is accomplished by inhibiting the loss of moisture already in the skin and by applying additional moisture to the skin. Applying water and then petrolatum or refined oil would work adequately, safely, and inexpensively, but without aesthetic appeal; the emulsion form makes skin care both effective and pleasing.

To formulate an emulsion, two immiscible liquids are brought together with sufficient energy so that one becomes finely dispersed in the other. One liquid is aqueous and the other is “oil.” This oil can be any mixture of liquid, molten semisolid, and molten waxy ingredients. The emulsion consists of both an external or continuous phase

Figure 1. Smectite hydration mechanism

and an internal or dispersed phase. Macroemulsions contain dispersed phase particles ranging from 0.1 to 50 μm . They are opaque, are thermodynamically unstable, and tend to separate. Microemulsions contain dispersed phase particles less than 0.05 μm . They are translucent and thermodynamically stable. They also are limited in the choice of acceptable ingredients and product rheology. Most creams and lotions sold for topical use are macroemulsions, the bulk of which are oil-in-water (O/W) with an aqueous external phase.

The first considerations in designing a cosmetic emulsion are its intended function and its required “feel” properties. For example, a hand lotion should spread without drag, feel silky, and rub in or be absorbed quickly. An O/W emulsion with low oil content is preferred. High water content provides moisture and facilitates quick rub-in. As the water evaporates, the oil phase coalesces into a thin, nongreasy film. Conversely, consumers prefer a heavier residual film from a facial night cream, equating this with increased efficacy. An emulsion of water-in-oil (W/O) can provide this richer residual feel while still providing moisture to the skin.

Requirements for any given product and its performance include ease of preparation, rheology, stability, and economics. These are particularly important when deciding between an O/W and W/O system. O/W emulsions generally penetrate more quickly and are less greasy, less emollient, faster drying, and less expensive to produce. They are chosen when fairly little fatty material is required or when the emulsion is used as a vehicle to deliver water-soluble active ingredients. W/O systems are associated with high emollience or with solvent action (e.g., cleansing creams). They also can be used as alternatives to anhydrous products such as ointments and sticks so that the costs of raw materials can be reduced, and their moisturizing potential can be increased by adding water (Ciullo 1980). Judicious selection of ingredients controls and modifies the actual feel and efficacy of emulsions. The choice of ingredients to provide specific desirable effects represents the merging of science and art by a skillful formulator.

The Water Phase

The water phase contains predominantly water, as expected. The water is preferably deionized, and has low bacteria content. Water is the vehicle for many functional ingredients in topical emulsions. These include emulsifiers (discussed later), water-soluble botanicals, vitamins, keratolytics, and proteins. Most common of the water-phase additives are the *humectants*, which serve a twofold purpose: (1) they inhibit surface desiccation in the container when an O/W product is left uncovered, and (2) they deposit a film that attracts moisture from the air to the skin, or conversely retards the rate of moisture loss from the skin to the air. Glycerin, butylene glycol, and propylene glycol are the humectants used most often in topical emulsions. Sodium pyrrolidone carboxylate and sodium hyaluronate are generally more effective, but because they are more expensive they are less commonly used.

Hydrophilic colloids are used in the water phase to thicken or stabilize the emulsion, especially at elevated temperatures where the oil phase liquefies. They form a colloidal structure that inhibits mobility and coalescence of the dispersed phase. They also participate in the interfacial film that coats dispersed oil-phase particles, providing charge or steric inhibition of coalescence (Lochhead 1994). In practice, hydrophilic colloids often are used as stabilizers to overcome deficiencies in emulsifier performance. They also are used to tailor viscosity, dispensing properties, and application properties of O/W emulsions. A variety of organic colloids, both natural and synthetic, are used in topical products, including xanthan gum, carboxyvinyl polymers, cellulose derivatives, alginates, carrageenans, and various acrylates.

The most widely used inorganic colloid is smectite clay, which is sold under the International Nomenclature Cosmetic Ingredient (INCI) name of bentonite or magnesium aluminum silicate and as sodium magnesium silicate in its synthetic form. INCI names are standardized generic designations applied to every raw material used in cosmetic products. The label of every product has a list of ingredients according to their respective INCI names. Smectite clay is used as an O/W emulsion stabilizer because of its unique colloidal structure. A macroscopic particle of smectite clay comprises many thousands of stacked or overlapped submicroscopic platelets approximately 1 nanometer thick by several hundred nanometers across. Platelet faces carry a negative charge from lattice substitutions, whereas edges have a slight positive charge from broken bonds and cation adsorption. Exchangeable sodium ions balance the overall negative charge.

When the clay is hydrated (i.e., mixed into water), water penetrates the area between the platelets, forcing them farther apart. Exchange ions then begin to diffuse away from platelet faces. Further penetration of water then proceeds in an osmotic manner until the platelets are completely separated. The speed with which platelet delamination occurs is related directly to the amount of energy introduced during hydration. Greater mechanical energy from mixer shear and thermal energy from heated water accelerate delamination. Once delaminating energy is removed, faces and edges of adjacent platelets are attracted ionically, forming a cohesive three-dimensional colloidal structure. Figure 1 illustrates the mechanism of clay hydration and colloidal structure building. The colloidal structure physically inhibits the movement and contact of the dispersed phase. The dispersed phase, stabilized in this manner, can be lipophilic as in an emulsion, solid as in a suspension, or gaseous as in a foam.

Although smectite clay is routinely classed as a thickener, it is relatively inefficient at this task compared to most of the organic hydrocolloids noted. Its utility in topical personal care products derives mainly from its stabilizing properties. By volume, its most common use is as an emulsion stabilizer in treatment, moisturizing, and sunscreen creams and lotions. It also has a long history in liquid foundations where it stabilizes the suspension of pigments and

Table 2. Common oil-phase emollients

Emollient	Functions
Hydrocarbons	
Mineral oils	Major vehicle in most products as emollient, as solvent, or as a diluent for fatty materials; oily feel
Petrolatum	Occlusive emollient; oil-phase thickener; sticky residual feel
Paraffin wax	Occlusive emollient; oil-phase thixotrope; poor oil absorption; sticky/waxy residual feel
Microcrystalline wax	Oil-phase thickener; high oil absorption; promotes occlusive, nongreasy residual films
Squalane	Oily emollient, nontacky skin lubricant
Fatty Alcohols	
Cetyl alcohol	Emulsion stabilizers; emollients; promote occlusive nongreasy residual films
Stearyl alcohol	
Cetearyl alcohol	
Fatty Acids	
Stearic acid (stearic/palmitic)	Soap emulsifier; oil-phase thickener; promotes nongreasy, residual films
Esters	
Isopropyl myristate	Relatively nongreasy liquid vehicles; can promote penetration to reduce oiliness/greasiness of residual films
Isopropyl palmitate	
Octyl octanoate	Emulsifiers; emollient waxes; oil-phase thickeners; semi-occlusive to occlusive
Glyceryl stearate	
Glycol/PEG* stearates	
Glycerides	
Caprylic/capric triglyceride	Bland emollients; promote spreading
Wheat germ glycerides	
Palm kernel glycerides	
Nut and Vegetable Oils	
Almond, corn, coconut, jojoba, olive, rapeseed, safflower, sesame, sunflower, wheat germ	Bland emollients; some prone to rancidity
Lanolin Derivatives	
Lanolin	Occlusive emollient; W/O [†] emulsifier; tacky residual feel
Lanolin alcohols	Occlusive emollient; more hydrophilic than lanolin; W/O emulsifiers; O/W [‡] emulsion stabilizers
Lanolin oil	Occlusive emollient; W/O emulsifier; much less tacky than lanolin; greater solubility in hydrocarbons than lanolin
Acetylated lanolin alcohols	Highly hydrophobic emollient; poor emulsifier; less allergenic potential for lanolin-sensitive skin
Silicone	
Dimethicone	Highly hydrophobic emollient; defoamer; barrier agent; somewhat oily residual feel
Alkyl dimethicone	Less oily feel; better hydrocarbon compatibility

* PEG = polyethylene glycol.

† W/O = water-in-oil.

‡ O/W = oil-in-water.

minerals (in addition to stabilizing the emulsion base), and in mechanical exfoliants where it suspends the abrasive particles. Using synergistic combinations of smectite clay with organic hydrocolloids, particularly carboxyvinyl polymers, is popular for optimum control of stabilization and rheology.

The water phase usually contains the emulsion's preservative system, although some partitioning between water and oil phases will occur. Bacteria propagate preferentially in the aqueous environment, so that water quality and the nature of water-phase ingredients dictate the type and level of preservatives required (Romanowski and Schueller 1995). Commonly used preservatives are methyl paraben, propyl paraben, phenoxethanol, imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, quaternary ammonium compounds, and isothiazolinones.

The Oil Phase

The oil phase provides emollience, imparting softness and flexibility to the skin while depositing a lipophilic film that inhibits water loss.

The oil phase also can be used for its solvent properties as in cleansing creams, for its protective properties as in barrier lotions, or to carry the actives as in vitamin creams. Organoclay—smectite clay that has been made oleophilic by reaction with a fatty quaternary ammonium compound—is used on occasion to stabilize and thicken W/O emulsions in a manner analogous to that of unmodified clay in O/W emulsions. The cohesion of the colloidal structure formed by delaminated organoclay is based on hydrogen bonding rather than ionic attraction. Table 2 is a very basic listing of common oil-phase ingredients and their primary functions and properties. The current selection of cosmetic-grade lipophiles is considerably more extensive, owing in great part to the proliferation of polyalkoxylated derivatives (PEG and polypropylene glycol) designed to nuance oleophilic and organoleptic properties.

The Emulsifier System

The ease with which the two phases can be emulsified is almost entirely a function of the interfacial tension between the two liquids.

Figure 2. Stabilizing interfacial film in O/W emulsion

Those having low interfacial tension will emulsify easily; those with high interfacial tension will emulsify with difficulty, if at all, and then only with the application of considerable mechanical energy. Introducing emulsifiers into either or both phases alters interfacial tension. Emulsifiers usually contain a polar group attached to a hydrocarbon chain, thus showing both hydrophilic and hydrophobic characteristics. The emulsifiers migrate to the oil-water interface, reduce the interfacial tension, and produce mechanically stable interfacial films. The polar groups are oriented toward the water phase and the hydrocarbon portion is oriented toward the oil phase. Since both oil and water wet the film of emulsifier, a difference in surface tension exists on the two sides of the film, causing it to bend. The side with the higher surface tension assumes a concave shape, and the emulsifier film bends until it completely envelops the particles of the dispersed phase. The nature of the envelope that forms determines whether the emulsion will be oil-in-water or water-in-oil.

Cosmetic emulsifiers are drawn from all four ionic classes of surfactants: an ionic, cationic, ampholytic, and nonionic. Of the anionic emulsifiers, historically the most widely used are triethanolamine stearate soaps, the orthophosphate esters of polyethoxylated fatty alcohols, and sodium cetyl sulfate. Stearate soaps generally are formed in situ, the fatty acid in the oil phase reacting with the organic base or alkali in the water phase. Anionic emulsifiers inhibit coalescence of the oil phase through a combination of charge repulsion and steric hindrance. The latter often is supplemented by incorporation of an oil-soluble polar compound such as cetyl alcohol. This results in a mixed interfacial film with greater rigidity and stability than that of a simple film, as illustrated in Figure 2. The anionic emulsifiers as a class, and especially soaps, tend to be unstable under conditions of low pH and in the presence of polyvalent cations or cationic surface-active agents.

Of the cationic emulsifiers, only quaternary ammonium compounds are used in cosmetic emulsions. Many quaternaries also possess bactericidal properties and adhere to skin and hair, forming lipophilic films. Incorporating a polar hydrocarbon such as cetyl alcohol is usually necessary to obtain a stable system. In general, quaternaries produce O/W emulsions, but various oil-dispersible compounds such as distearyldimethylammonium chloride can be used to produce W/O emulsions. Some quaternary compounds may be skin irritants. As a class, quaternaries are unstable under alkaline conditions. Surface activity and emulsifying power of ampholytic surfactants depend on pH. These compounds are anionic at high

pH, cationic at low pH, and have an isoelectric point at approximately neutral pH, at which they behave as nonionics. At this point their solubility, surface activity, and emulsifying power are minimal. The use of ampholytic and cationic emulsifiers in cosmetic emulsions is not widespread.

In nonionic emulsifiers, the hydrophobic portion, which may be alkyl, alkylaryl, or a silicone, is linked to the hydrophilic portion of the molecule, which can be a simple alcohol group, a polyol such as glycerol or sorbitan, an amino glycol such as diethanolamine, or a polyglycol such as polyethylene glycol or polypropylene glycol. Nonionic emulsifiers range from primarily oil-soluble compounds suitable for producing W/O emulsions to primarily water-soluble compounds for producing O/W emulsions. It is common to use both a hydrophilic and a lipophilic nonionic in an emulsion system for a more rigid interfacial film, therefore achieving the greatest stability. Nonionic emulsifiers inhibit coalescence of the dispersed phase in O/W emulsions primarily by steric hindrance.

Emulsifier Selection

Once the required properties of an emulsion are determined and oil- and water-phase components have been selected accordingly, the most difficult task is to identify emulsifiers that provide ease of emulsification and product stability at minimum cost.

The first and most popular or organized approach to emulsifier selection was the HLB method. The term *HLB* is derived from the expression “hydrophile-lipophile balance.” Any surface-active agent (more strictly nonionics) can be assigned an HLB number that denotes the relative balance of hydrophilic and lipophilic characteristics, thus defining its behavior at an oil-water interface. The HLB number is a direct function of the relative amount of the hydrophilic portion of the molecule, so low values imply poor water solubility but good oil solubility, and vice versa for high values. In general, emulsifiers having HLB values of 3 to 6 will be suitable for W/O emulsions, whereas materials having values of 7 to 18 will produce O/W emulsions. The individual values of given emulsifiers are algebraically additive, so HLB values for mixtures of compatible emulsifiers can be calculated. A shortcut in emulsifier selection is the use of prepared blends of low- and high-HLB emulsifiers and emulsion stabilizers (e.g., glyceryl stearate and PEG-100 stearate). Many are available and serve as a convenience in emulsion formulation. Despite its value as a guide to effective emulsion selection, the HLB method does not necessarily predict which emulsifier system will provide the optimum long-term stability under all anticipated storage conditions. This may explain the widespread use of smectite clay and the organic hydrophilic colloids to ensure product stability.

Emulsion Production

Physically preparing an emulsion involves two basic considerations. The first is the order of addition of the two phases. For W/O emulsions it is preferable to add the water phase to the agitated oil phase. For O/W products the analogous method of adding oil to the water phase is commonly employed, but an inversion method is sometimes preferred. The latter involves adding the water phase to the oil phase slowly, creating a W/O emulsion initially. At a certain water-phase volume, the emulsion will invert to O/W and the remaining water phase can be added rapidly. Emulsions made by this method are usually more stable. It is possible to use less emulsifier, making the technique more economically attractive.

The second consideration is the temperature of the two phases. In typical emulsions, containing waxy or semisolid material in the oil phase, heat is mandatory. Both phases are heated to at least 5°C above the melting temperature of the ingredient with the

highest melting point. The phase that will be added to the other is heated an additional 2° to 3°C to allow for cooling during addition.

Emulsions usually are prepared in jacketed tanks so that they can be cooled rapidly with cold water. For lotions, mixing commonly takes place while cooling to about room temperature. For creams, mixing much below the gelation or solidification point of the oil phase is impractical because of the increase in product viscosity and the increased tendency toward aeration. When cooled without agitation, however, the rate of cooling from the center to the edges of the processing tank can vary considerably. Resultant differences of size and aggregation of oil-phase crystallites or droplets can produce large variations in physical properties within the tank. When this happens, the batch is made uniform by passing through a homogenizer after cooling.

COLOR COSMETICS

Color cosmetics encompass foundations, blushes, eye-area cosmetics, lip colorants, and nail enamels. Table 3 summarizes the forms in which these products are produced and the minerals commonly used therein. Minerals used by the cosmetics industry, including the smectite clays and organoclays used as stabilizers and thickeners, must meet particular standards of mineralogical, chemical, and bacterial purity. Levels of bioavailable (acid-soluble) heavy metals are strictly controlled, typically no more than 3 ppm As and 12 to 15 ppm Pb. Bacteria counts are generally restricted to less than 1,000/g, but much lower levels often are mandated by purchasers. These lower limits are achieved, when necessary, by using bulk sterilizing treatments such as gamma irradiation. High mineral whiteness or brightness generally is required.

Colorants

Several forms of colorant are used in color cosmetics. Dyes are organic compounds that are soluble in the medium to which they are added. They are used sparingly in color cosmetics, other than lip products, to avoid staining skin or nails. Pigments are insoluble in the medium to which they are added. They may be organic or inorganic. Toners are organic pigments made by precipitating water-soluble dyes as insoluble metal salts. *Lakes* are composite pigments made by precipitating the metal salt of a dye onto the surface of an insoluble organic (e.g., rosin, aluminum benzoate), inorganic (e.g., alumina, blanc fixe, titanium dioxide [TiO₂], zinc oxide), or mineral (e.g., calcium carbonate, kaolin, talc) substrate. Organic pigments generally provide clean bright colors; unlike inorganic pigments, however, they have overall poorer chemical stability, lightfastness, and bleed resistance. Pure inorganic pigments tend to be more opaque and subdued, imparting a creamy, rather than sharp, color effect. Those used most commonly in cosmetics are TiO₂ for whiteness and iron oxides (e.g., Fe₂O₃) for earth tones. Nacreous pigments, and powdered aluminum and bronze, often are used for purely decorative effect in nail and eye-area cosmetics.

Nacreous or pearlescent pigments are thin, transparent platelets of high refractive index that partially transmit and partially reflect light. The pearlescent effect is due to specular reflection from the broad surfaces of transparent platelets and the near-parallel orientation of overlapping platelets. Light transmitted through upper platelets is partially reflected by lower platelets. Pearly luster results from the dependence of reflection on viewing angle and the sense of depth created by reflection from successive layers.

The original pearl pigment was derived from fish scales as platy crystals of guanine and hypoxanthine. This pigment remained unrivaled in luster for approximately 300 years, until the refinement of crystallization processes for platy basic lead carbonate in the 1950s. Bismuth oxychloride was developed as a nontoxic alterna-

Table 3. Color cosmetics

Cosmetic	Common Product Form	Mineral Used
Foundation	Emulsion, pressed powder	Smectite, talc, kaolin, mica
Blush	Pressed powder	Talc, kaolin, mica
Eye shadow	Pressed powder, anhydrous cream	Talc, kaolin, mica, organoclay
Mascara	Emulsion, solvent suspension	Smectite, organoclay
Eyeliners	Aqueous suspension	Smectite
Lip colorant	Wax-based stick, ointment	Organoclay, mica
Nail enamel	Solvent solution	Organoclay
Pencils	Wax-based stick	Talc, mica

tive to lead carbonate and is still used in color cosmetics, although its relatively poor light stability may require the inclusion of a UV absorber. Bismuth oxychloride provides a silvery-gray pearlescence, varying from a soft luster to a bright sparkle depending on crystal size. For pearlescent and metallic effects in a range of colors, nacreous pigments are used. These colorants take advantage of the lamellar shape and optical clarity of mica.

White nacreous pigments are made by forming a uniform coating of TiO₂ on mica platelets. Mica serves as a transparent template so that the high refractive index of TiO₂ assumes the required platy shape. Pearlescence is optimal when pigment optical thickness (platelet thickness multiplied by refractive index) is in the 100 nm (blue white) to 140 nm (yellow white) range. Use of thicker platelets produces interference colors; the interaction of reflections from upper and lower surfaces of the platelets creates light interference. A maximum reflection occurs when the wavelengths of light from these two reflections are in phase. A reflection minimum occurs when the wavelengths are exactly out of phase, canceling out each other.

Nacreous pigments provide a two-tone metallic effect. The reflected (specular) color is seen as a highlight. The background color at nonspecular angles is created by the diffuse reflection of the transmission color. The complementary reflection–transmission colors as a function of pigment optical thickness range in a continuous spectrum from blue/white at 100 nm to magenta/green at 250 nm to green/red at 370 nm.

Color effects of nacreous pigments are supplemented by overcoating TiO₂-mica platelets with a thin transparent film of light-absorbing colorant, for example, iron oxide for yellow, ferric ferrocyanide for blue, chromium oxide for green, and carmine for red. The combination pigments thus produced can have matched reflectance and absorption color or they can be two different colors. When colors match, one color is seen at all viewing angles, with metallic highlights at specular angles. A two-color effect is achieved with different colors. Combination interference–absorption pigments are made in the gold to red range by coating Fe₂O₃ directly onto mica.

Minerals

In foundations, skin texture and general aesthetic appeal are improved principally by mineral additives, which serve several important functions:

- Provide a smooth surface
- Facilitate even pigment coverage and adherence to the skin
- Absorb skin oils and moisture to control sheen and prevent caking of pigments
- Provide a uniform optical base for pigments
- Ensure uniform pigmentation

Table 4. Treatments for minerals and pigments

Treatments	Function
Physical Adherents	
Micrometer, submicrometer spheres: silica, nylon, polymethylmethacrylate	Improved lubricity, light diffusion
Surface Coatings	
Silicone oils (dimethicone)	Improved oil dispersibility, color development
Waxes	Improved oil dispersibility, lubricity, powder compressibility
Surface Precipitates	
Amino acids (N-acyl amino acids, N-lauroyl lysine)	Improved skin adhesion, lubricity, powder compressibility
Metal soaps (Zn, Mg, Al; stearates, myristates)	Improved skin adhesion, lubricity, powder compressibility
Lecithins	Silky skin feel, improved powder compressibility
Surface Reactants	
Silicon-based (methicone, alkyl silanes)	Improved oil dispersibility
Titanate esters	Improved oil dispersibility
Fluorochemicals (perfluoroalkyl phosphate, polyperfluoroethoxymethoxy PEG-2 phosphate)	Surfaces are both hydrophobic and lipophobic, resistant to water, perspiration, sebum

Table 5. Composition of O/W liquid foundation

Composition by Phase	Wt %
Water Phase	
Water	62.0
Magnesium aluminum silicate	1.2
Cellulose gum	0.2
Butylene glycol	8.0
Polyalkylene glycol laurate	5.0
Potassium cetyl phosphate	1.5
Preservative	0.4
Pigment Phase	
Talc	5.0
Kaolin	1.3
Titanium dioxide	6.5
Yellow iron oxide	0.5
Red iron oxide	0.3
Black iron oxide	0.1
Oil Phase	
Isostearyl neopentanoate	2.5
Cyclomethicone	2.5
Cetyl alcohol	2.0
Steareth-2	1.0

Only three minerals are routinely used in this way: talc, kaolin, and mica. Talc is, by volume, the most commonly used mineral. It is typically the major component of face powders, blushes, and eye shadows. Talc is naturally oleophilic–hydrophobic and so aids in skin adhesion and water repellency. Cosmetic-grade talc must be pure and white, and it is usually relatively coarse (nominally 200 mesh) so that its characteristic slip and lubricity are palpable. Fragrance retention is also a desirable attribute for anhydrous preparations. Some talcs are better than others in absorbing and holding unchanged the fragrances that are used to add appeal and mask characteristic odors of other ingredients. Water-washed kaolin imparts and maintains a smooth, matte appearance. It prevents shine and pigment caking by absorbing skin oils and perspiration. It also eliminates the slight sheen imparted by some talcs.

Calcium carbonate also provides absorption and a matte finish, along with greater opacification. Milled muscovite mica is used in color cosmetics, but much more in treated form as a pigment than as a functional mineral. Sericite, a naturally fine-grained form of muscovite, is used for its combination of talc-like properties and silky shine.

Cosmetic-grade pigments and minerals are available with a variety of surface treatments (Table 4) that benefit properties in both processing and the finished product (Hollenberg 2002). Treatments generally impart or enhance hydrophobicity, which improves dispersion in nonaqueous vehicles and pressability in pressed powders. In the cosmetic product, the treatments improve lubricity and feel, uniformity of coverage, skin adhesion, optical appearance, water repellency, and wear properties.

Foundation

The functional use of foundation (liquid or powder) is to visually improve skin appearance by covering surface imperfections and uneven coloration. The goal is to provide visually smooth skin with even, but natural-looking skin tone. Its decorative use adds color to either highlight or subdue facial features or contours, or simply to decorate.

Liquid foundations are emulsions, as previously described, in which the pigment phase (pigments and minerals) is suspended uniformly. Selected water- and oil-phase ingredients provide emollience; deliver active ingredients as required (e.g., sunscreens, botanicals, antioxidants); and facilitate smooth and even application, uniform coverage, skin adhesion, and long wear. W/O emulsions are used for greater emollience and water resistance, but foundation emulsions are usually O/W, most of ten using anionic emulsifiers for optimum pigment dispersion, skin feel, spreading, and blending. These products are made by dispersing the pigment phase, often preblended and milled, into the water phase before emulsification. Smectite clay traditionally is used as a stabilizer because it ensures stable and uniform suspension of both the pigment phase and the oil phase. Table 5 gives an example of the composition of an O/W emulsion foundation.

In the past, foundation powders were mostly talc, with just enough pigmentation, and application and adhesion promoters to achieve the desired effect. In most cases, these have been replaced by pressed powders, in which binders, texturizers, emollients, and other additives provide a convenient form with good storage

and application properties. Table 6 summarizes the additives and their functions. It is apparent from this table that some materials used as binders serve other functions as well. Most pressed powders are applied with a dry puff or cosmetic sponge. So-called two-way pressed powders are applied either dry or with a wet cosmetic sponge. These are formulated with surface-treated pigments and minerals, as necessary, to prevent water from penetrating the pressed cake. Pressed powder blushes are similar in composition to pressed powder foundation products, but with a wider range of colors. These are normally applied with a brush, so binders and other additives are adjusted accordingly for proper application. Although foundations are used to make the skin appear as smooth and uniformly colored as possible, blushes are used for more specific optical effects. Blushes harmonize the impact of lipstick and eye shadow and change the apparent contours of the face by highlighting the cheekbones. Pressed powder eye shadows are also similar in composition to foundations, but with more emphasis on color and pearlescence. Pigmentation highlights or subdues eye depth and color. Pearlescent and nacreous pigments are used more often than in other pressed powders. This places added demands on the formulation, because even coverage and durable skin adhesion are essential to a void creasing on the eyelid. Table 7 gives examples of pressed powder formulations.

Other Decorative Cosmetics

Other than mica-derived nacreous pigments, the only minerals routinely used in other decorative cosmetics are smectite clays and their organoclay derivatives. Eyeliners are usually aqueous pigment suspensions used to frame the eye, accentuate eye shadow, and change the apparent shape and size of the eyes. In addition to wetting agents and humectants, they contain smectite clay or an organic gum for suspension stability and a polymeric film former such as polyvinylpyrrolidone (PVP) or polyvinyl alcohol (PVA) to hold the pigment in place after application and drying. Some waterproof eyeliners are pigment suspensions in a hydrocarbon solvent. These are stabilized with an organoclay and contain a solvent-soluble film former. Mascara is used primarily to give the appearance of thicker and longer eyelashes. The most durable and smudge-proof products are typically O/W emulsions stabilized by a smectite clay or organic gum made water resistant with an acrylic, polyvinyl acetate, or polyurethane emulsion polymer. W/O mascaras are offered as waterproof products, as are solvent-based suspension products. The latter are similar to solvent eyeliners, which are stabilized by organoclay, but generally with higher wax content. Because of their proximity to the eye, eyeliners and mascaras must contain suitable preservatives.

Lipstick and lip gloss are essentially pigmented oily suspensions thickened with waxes. Organoclays sometimes are included to ensure uniform pigment suspension during manufacture while the product is in a fluid molten state. Most nail lacquers are based on solvent solutions of nitrocellulose and amino or epoxy resin. Nitrocellulose provides the film, and the resin and plasticizers optimize film adhesion, hardness, flexibility, and gloss. Organoclay, in particular stearalkonium hectorite, often is used in these products to suspend pigments and to improve rheology so that the lacquer applies easily and uniformly without running or leaving brush marks. The “lead” in cosmetic pencils is basically a rigid, pigmented, wax stick with waxy ingredients that thicken emollient oils. “Japan wax” is a common ingredient because of its adhesive properties. An organoclay may be used in the same capacity as in lipsticks. Mica and talc are included in some products to adjust payout onto, and adhesion to, the skin. Cosmetic sticks are produced with colors suitable for eye and lip areas and as alternatives to powder blushes.

Table 6. Additives in pressed powders

Additive	Function
Metal stearate (most often Zn or Mg)	Impart water repellency, improve skin adhesion and smoothness
Magnesium carbonate	Fragrance absorbent/carrier
Texturizer (polymer powders: nylon, polytetrafluoroethylene, acrylates, silicone; boron nitride, starches, surface-treated minerals)	Improve application properties, skin feel and texture
Antibacterial (preservative powders: parabens, imidazolidinyl urea, etc.)	Prevent bacterial growth from skin moisture or water introduced from applicator
Fragrance	Mask subtle odors from other ingredients, impart pleasant odor
Emollient (oils, fats, waxes)	Improve application properties, skin feel and texture, skin adhesion, skin suppleness and smoothness; impart water repellency
Binder (kaolin, micronized smectite, fats, waxes, polymer powders)	Aid ingredient compression and adhesion, enhance pigmentation, allow smooth pickup by applicator, allow smooth transfer to skin, add water resistance

Table 7. Composition of pressed powders, wt %

Ingredients	Pressed Powder Type	
	Foundation	Eye Shadow
Powder Phase		
Talc	63.4	None
Sericite	15.0	10.0
Calcium aluminum borosilicate	10.0	None
Zinc stearate	5.0	6.0
Polytetrafluoroethylene powder	None	3.0
Yellow iron oxide	0.6	None
Red iron oxide	0.7	None
Black iron oxide	0.4	None
Nacreous gold (mica/TiO ₂ /red iron oxide)	None	40.0
Bismuth oxychloride	None	10.0
Ultramarine blue	None	10.0
Chromium oxide green	None	9.0
Preservative	0.4	0.4
Binder Phase		
Sorbitan sesquoleate	0.5	None
Isoeicosane	4.0	7.5
Polyisobutene	None	3.5

Masks

The most mineral-intensive cosmetic compositions are masks. The conventional mask product is the “mud” mask used to cleanse facial skin by means of the absorptive capacity of clays. These products are heavy clay pastes that are coated onto the face and allowed to dry to a mask-like covering. Dirt and oils are absorbed into the clay, which is subsequently rinsed off. A mask of this type provides a tightening effect on the skin (from the contraction of the dried clay film) that the consumer associates with effectiveness. In addition to this tightening sensation and to the actual cleansing, the mask is expected to apply easily, to dry quickly after application, to rinse or wash off without much effort, and to not irritate. Kaolin clay is preferred because it provides good absorption and it has a mild acidic

Table 8. Composition of facial masks, wt %

Ingredient	Clay Mask	Peelable Mask
Water	53	66
Butylene glycol	8	10
Kaolin	30	10
Bentonite	5	2
Oat flour	2	none
Sodium lauroyl sacosinate	1	2
Aloe vera	1	none
PVA	none	10
Preservative	qs*	qs

* qs = quantity sufficient.

pH, which is skin compatible. Although it has a higher absorptive capacity, bentonite typically is used to supplement kaolin rather than serving as the primary absorbent. Bentonite is alkaline, which may cause skin irritation, and its swelling properties generally restrict the amount that can be introduced in to water before the composition becomes too viscous to mix. Bentonite is useful, however, in preventing separation of water from the paste. Talc is sometimes used in relatively small amounts to improve spreading properties while reducing the tendency of the dried mask to flake. Film-forming polymers also are used for this purpose.

The fundamental ingredients for a clay mask are clay and water, which alone would provide an effective but inelegant product. In practice, any number of additives are employed. Humectants contribute plasticity to the dried clay film so that it does not easily crumble off the face. They also facilitate rewetting the film for easy removal. Small amounts of surfactant improve cleansing effectiveness and ease of removal. Botanicals, vitamins, proteins, medications, and emollients may be added to improve skin condition.

Liquid or peel-off masks were developed for neatness and as a more convenient alternative to mud masks. These are based on film-forming latexes or polymers such as PVA or PVP that provide a sensation of skin tightening after the mask dries and the polymer film contracts. Only limited amounts of clay can be used in these preparations so as not to diminish the integrity of the polymer film. Absorptive cleansing therefore is minimized, although it can be supplemented by surfactants.

Mask products are now common for other areas of the body so that the term *mask* is used more conceptually—a product left on the skin (or hair) for at least several minutes to provide treatment, cleansing, or regenerative functions before its removal. These products are typically moisturizing or treatment emulsions that may or may not contain absorptive clay. Table 8 lists examples of facial mask compositions.

REGULATORY CONSIDERATIONS

Regulation of cosmetics production and sales in major global markets directs or guides nearly all aspects of product composition, manufacture, and sale. Purity is the primary issue for raw materials. Considerations are chemical purity and absence of unacceptable residual solvents or by-products, control of heavy metals content, and control of bacteria content. As with all raw materials and all finished products, control of bacteria associated with minerals is paramount. Because minerals do not readily support bacterial propagation, reduction in natural bacteria levels is, if necessary, relatively straightforward and usually is accomplished by heat treatment while milling or with sterilants such as ethylene oxide or

gamma irradiation. A historical requirement is to have fewer than 1,000 organisms/g or mL and the absence of certain staph, *Candida*, *Pseudomonas*, and other gram-negative and enterobacteria in both raw materials and finished product. Raw materials used in cosmetics for the eye area, infant care, and intimate hygiene products must be limited to 100 organisms/g or mL. Cosmetics manufacturers must contend with requirements to improve bacterial control with the smallest possible amount of a limited number of preservatives that are available. The trend is to require raw material suppliers to improve bacterial control to as low as (or lower if possible) 100 organisms/g or mL for all uses.

Although silica is a general concern for most consumers of mineral raw materials, it is not a major consideration in the cosmetics industry because the minerals used by cosmetics manufacturers must conform to a level of purity that minimizes or eliminates residual crystalline silica. In addition, these minerals are not used in compositions that liberate respirable particles.

The use of talc in cosmetics continues to be inhibited to a certain extent by the perception that it is linked in some way to asbestos or asbestiform minerals, which may cause lung cancer if inhaled. Although purity standards for talc preclude the presence of asbestiform particles, the use of talc in dusting powders is not common today. Although unsubstantiated and technically refuted, talc is likewise subject to a persistent association with ovarian cancer.

TRENDS AND OPPORTUNITIES

Consumer interest in “natural” products continues to increase, especially for those used in personal care. Minerals used in cosmetics are fundamentally natural and will continue to be exploited as such. It may be ironic that consumer interest in using minerals that are arguably less natural (i.e., affixed with surface treatments for enhanced aesthetic effects) also continues to increase.

Conventional uses for cosmetic-grade minerals continue to grow along with their major application—emulsion products. Growth in sales of creams and lotions tends to exceed that of other product categories. Opportunities for future growth lie in providing additional functionality and value, as with surface treatments, and more significantly, in the rapidly expanding cosmetics markets in developing economies in Latin America, Eastern Europe, and China.

Electronic and Optical Materials

Stanley T. Krukowski

In this chapter, minerals for electronic and optical uses are described in two sections—quartz, and minerals other than quartz. Quartz has been used for radio communications since the beginning of the 20th century. Its first major use was in frequency control. With increased interest and study, the physical properties of quartz were exploited in electronics: dielectric, piezoelectricity, and pyroelectricity. Quartz is transparent in both the infrared and ultraviolet ranges of the spectrum. Its high optical activity makes quartz useful in optical instruments. High-quality quartz deposits were eagerly sought; however, when artificial synthesis of quartz crystallization was discovered, an entire new industry emerged.

Contributions made in the fields of electronics and optics by minerals other than quartz also are covered in this chapter. These minerals and their applications are many and given only briefly here; the reader is referred to the commodities chapters of particular minerals for specific uses in these fields.

QUARTZ

The properties of quartz crystal that make it useful for radio communications were discovered in 1918. Since that time, an industry for mining and processing natural quartz crystal has grown, matured, and been replaced almost entirely by new technology. Quartz crystal is still involved, but it is grown rather than mined.

An economic summary of the commercial growing of quartz crystals has a place in a book for the mineral engineering industry because quartz crystals have long been an important commercial mineral. In addition, natural quartz is still the raw material for cultured quartz; that is, quartz crystals grown artificially.

In the first half of the 20th century, nearly all natural quartz crystals used for electronics and optics came from Brazil. The larger pieces that met rigorous standards of quality were used for electronic and, to a lesser extent, optical components. Smaller pieces and fragments were used for vitreous silica. The need for high-quality material in relatively large quantity led the U.S. government to sponsor related research, including exploration programs, in the 1940s. No deposits were found that met the very rigid requirements for electronic-grade quartz, but related projects resulted in the development of a process for the manufacture of beautiful crystals of prescribed shape, size, and quality. Domestic deposits of appropriate quality were identified for use as raw materials in processing cultured quartz.

Development of the cultured quartz crystal illustrates how successfully technology can adapt a mined commodity to increasingly sophisticated uses. This success was foreshadowed by the experiments of Giorgio Spezia (1908), an Italian geologist who studied the relative effects of temperature and alkalinity on the solubility of quartz.

Frequency control in modern radio equipment is achieved most often by the presence in the circuit of a separately added crystal. The initial discovery in 1918 was responsible for the existence and growth of the quartz industry. The quartz is a carefully oriented and prepared slice from a crystal, not a crystal as recognized by a rock hound or seen in a museum.

Quartz belongs to a class of materials called *dielectrics*: substances that do not conduct an electric current but permit electric fields to exist and act across them. Quartz shows the *piezoelectric effect*, which means that when a quartz plate is mechanically deformed against its natural stiffness, one of its surfaces becomes negatively charged and the other becomes positively charged. When the plate is released quickly from the stress, the charges disappear as the plate regains its original shape, but because of mechanical momentum, the plate deforms in the opposite direction (to a lesser amount) and the surfaces correspondingly become charged in the opposite direction. Thinly coating the two surfaces with metal and attaching flexible wires brings these charges into an electronic circuit. If the surfaces are suddenly electrically charged by movement of current through the wires, the converse piezoelectric effect occurs and the plate deforms. An alternating current flowing through the wires responds to this mechanical oscillation. Controlling the thickness of the plate varies its mechanical vibration frequency through a wide range. Cady (1964) and Mason (1964) discuss in greater detail how quartz operates to control frequencies.

One type of quartz plate, the AT-cut, has a precise orientation with respect to the crystallographic axes of the crystal and vibrates on a microscopic scale much as a book would deform when placed flat on a table and the top cover is moved parallel back and forth with the hand. At least 17 other orientations have been studied, some of which have preferred uses in various applications (Cady 1964).

The quartz crystal industry has three main segments (excluding fused quartz and quartz used for optical purposes):

1. *Natural electronic-grade quartz crystals* are mined quartz crystals suitable for fabrication into piezoelectric units. Zlobik

Table 1. Chronology of quartz crystal industry development

Date	Comment
1918	Discovery of the piezoelectric effects of quartz crystal
1921	Application of the piezoelectric effects of quartz crystal in the circuitry of radios
1948	Establishment of a quartz crystal commodity stockpile by the U.S. government
1952	U.S. consumption of natural quartz crystal at an all-time high of 228 t
1958	First commercial production of cultured quartz crystal
1970	Cultured quartz crystal production exceeds imports of natural quartz crystal
1971	Cultured quartz crystal consumption surpasses natural quartz crystal consumption
1976	Surge in the use of quartz crystal, both natural and cultured, because of citizens band radio sales and later decline because of change in technology in citizens band radio circuitry
1977–1990	Continued replacement of natural quartz crystal by cultured quartz crystal to the point that virtually no natural crystal is used in electronic and optical applications. New developments in the use of quartz crystals in all kinds of electronic devices, from watches to microprocessors in automobiles, toys, cellular phones, etc.
1997	Termination of natural quartz crystal mining in the United States
2000	U.S. Geological Survey (USGS) discontinues reporting U.S. cultured quartz crystal production to avoid disclosing company proprietary information
2003	Only two U.S. manufacturers of synthetic quartz crystals continue to operate

(1981) estimated the ratio of suitable commercial-grade quartz crystal to total excavated material to range from 1:1,000 to 1:1,000,000, depending on the deposit.

2. *Lascas* is mined quartz usable as feedstock in the production of cultured quartz. Approximately 0.63 kg of *lascas* is required to produce 0.45 kg of cultured quartz.
3. *Cultured quartz* is produced from *lascas* feedstock in a process in which crystals are grown in an autoclave under controlled conditions of heat, pressure, and time. It is estimated that 0.45 kg of cultured quartz is equivalent to 1.4 to 4.5 kg of natural quartz crystal in yield of commercial quartz suitable for slicing into piezo-electric units.

The chronology of the development of the quartz crystal industry, both natural and cultured, is given in Table 1.

Production and Consumption

Lascas mining ended in Arkansas by the end of 1997. In 2004 no companies reported the production of cultured quartz in the United States, a trend that began in 2001; companies considered production figures to be proprietary information. The capacity for the manufacture of cultured quartz still exists in the United States; feed material, however, consists of imported and stockpiled *lascas*. The year 2000 was the last time that U.S. manufacturers reported cultured quartz production statistics to the USGS. Producers reported fabricating 189 t of cultured quartz crystal in the United States in 2000. Fourteen out of 26 companies responded to a USGS survey intended to monitor cultured quartz crystal in 2003; the USGS withheld these statistics, however, to avoid disclosing company proprietary data. The last time that the USGS reported apparent consumption for cultured quartz was 2000, when operators reported using 146 t to fabricate quartz crystal devices (Dolley 2003).

As of September 30, 2004, the uncommitted inventory—that is, the quantity of mineral material held in the National Defense

Stockpile (NDS)—of natural quartz crystal was 7 t. The amount of committed inventory (materials sold or traded from the stockpile, either in fiscal year [FY] 2004 or in prior years, but not yet removed from stockpile facilities as of September 30, 2004) is 43 t of natural quartz crystal (Dolley 2005). There are 7 t of natural quartz crystal authorized for disposal from the NDS. This refers to quantities that are in excess of the stockpile goal for a material and for which Congress has authorized disposal over the long term at rates designed to maximize revenue but avoid undue disruption of the usual markets and financial loss to the United States. The disposal plan for FY 2004 accounted for 68 t of natural quartz crystal in the NDS, indicating the total amount of a material in the NDS that the U.S. Department of Defense was permitted to sell under the Annual Materials Plan approved by Congress for FY 2004 (from October 1, 2003, through September 30, 2004). For mineral commodities that have a disposal plan greater than the inventory, actual quantity is limited to remaining disposal authority or inventory. Finally, disposals for FY 2004 amounted to 54 t of natural quartz crystal, and refer to material sold or traded from the NDS in FY 2004 (Dolley 2003).

Most quartz crystal is used in piezoelectric and optical applications such as quartz resonators in aerospace, commercial, and military bandpass filter applications requiring high selectivity and very high stability. For many applications requiring only moderate stability, quartz resonators offer a combination of high performance, small size, and low cost. Quartz resonators also are used for less-demanding applications such as timing signals for electronic circuits in automotive, consumer, and industrial products (Dolley 2003).

Exports and Imports

The United States is completely reliant on imports of quartz *lascas* primarily from Asia followed by Brazil, Germany, and Madagascar; Canada is increasingly becoming an important source for natural quartz crystal. Production of cultured quartz has come increasingly from areas outside the United States, particularly from China, Japan, and Russia, as well as Belgium, Brazil, Bulgaria, England, France, Germany, and South Africa (Dolley 2003, 2005). The United States and Japan have been the major importers and consumers of *lascas* as well as major producers, consumers, and exporters of cultured quartz crystals. Little is known of the cultured quartz operations in China, Eastern Europe, and the Commonwealth of Independent States (CIS).

Prices and Trends

Prices of quartz material vary considerably; *lascas* typically sells well below the price of cultured quartz. The USGS (Dolley 2003) reported an average value for as-grown cultured quartz estimated at about \$81/kg in 2003. Also, the reported average value of lumbered quartz, which is as-grown quartz that has been processed by sawing and grinding, was estimated at about \$176/kg.

The electronic-grade quartz crystal industry ranges from the fully integrated producer/consumer (involving base-mineral production, cutting of blanks for piezoelectric units, and fabrication into finished electronic units) to companies that are involved only in segments of the industry. Pricing in the industry reflects this segmented or captive structure depending on where the transfer, or sale, of the mineral takes place.

Demand for quartz crystal devices should continue to grow, and as a result the demand for quartz crystal also should remain strong long into the future. The consumer electronics industry, particularly in the industrialized nations, will continue to foster production on a global scale.

Production of Cultured Quartz

The early history of producing large, high-quality quartz crystals in the laboratory and factory, and the general manufacturing process, was described by Waesche (1960).

Today four operators in the United States have the capacity to produce cultured quartz crystal; one reported in 2003, however, that it was no longer in production, and another reported that it was no longer in business. The production statistics for the remaining two manufacturers were withheld for proprietary reasons. Other countries producing cultured quartz crystal are Belgium, Brazil, Bulgaria, China, England, France, Germany, Japan, Russia, and South Africa.

The manufacturing process involves hydrothermal growth using an aqueous solution at elevated temperature. The process is similar to the hydrothermal action that develops ore bodies and crystal formations in the earth's crust. A vertical steel vessel with suitable internal fittings and pressure gage, safety blow-off valve, thermocouples, and a source of electrical heating is charged with (1) nutrient material (lascas) to about one quarter of its volume; (2) dilute alkaline solution to about three quarters; and (3) an array of seed plates. The vessel is closed, its contents brought to about 350°C, and a high pressure is produced. The heat source is adjusted to provide a temperature differential between the area of dissolution and the area of deposition and growth. Conditions of constant temperature and pressure are maintained for a period of weeks or longer. The status of the growing crystals is monitored using radiography with cobalt-60.

Vessels up to 254 mm I.D. (inside diameter), and capable of operating at up to 275.8 MPa, are in use. Figure 1 shows manmade quartz crystals in an autoclave or reaction vessel.

Table 2 compares the growth conditions used in the past by two major U.S. producers (Sawyer Technical Materials, LLC [formerly Sawyer Research Products, Inc.] and Thermo Dynamics, Inc.).

Although no deposits have been mined for natural electronic-grade quartz in the United States (Waesche 1960), high-purity U.S. quartzite (lascas) has been used successfully in producing cultured quartz.

Seed

The earliest seed plate that had considerable attention was a thin plate cut parallel to the minor rhombohedral face, often identified as r or as $\{0111\}$ by Bravais symbols, a face that makes an angle of $38^{\circ}13'$ with the c axis. This seems a reasonable choice because the plate should grow parallel to itself. The AT-cut plate (Cady 1964), whose surface makes an angle of $35^{\circ}15'$ with the c axis, is perhaps the most used for frequency-control oscillators. This choice of seed orientation was patented (Friedman and Tuttle 1951) particularly for promoting rapid crystalline growth. The patent states that this orientation grows "much more rapidly than seed plates cut at other angles." It turns out, however, that in the alkaline mediums used, growth of the minor rhombohedral face terminates prematurely. The major rhombohedral face grows much slower, the prism faces grow at a negligibly slow rate, and the crystal ultimately becomes a more or less square bar (depending on how the seed was supported) elongated in the c direction, lengthening slowly.

In 1954, a newer seed type called the Y-bar seed (Jaffe and Turobinski 1960) was invented: an elongated quartz crystal seed bar with its length extending substantially perpendicular to a crystallographic x axis and substantially perpendicular to the z axis of the crystal; the seed bar is small in cross-sectional dimension perpendicular to its length. In piezoelectric engineering, the x , y , and z axes are mutually perpendicular, the x axis is one of the a axes, and the z axis is the c axis in the hexagonal system to which quartz

Table 2. Comparison of growth conditions of two major U.S. producers

Growth Condition	Sawyer Technical Materials, LLC	Thermo Dynamics, Inc.
Solution	0.83 molar Na_2CO_3	1.0 molar NaOH
Percentage of fills, %*	76	80–82
Growing temperature, °C	350	354.5
Dissolving temperature D , °C	+5–20	+26.7–37.8
Pressure, MPa	82.7	158.6
Time, days	42	28–30

Source: Ober 1994.

* Percentage of the internal volume of the vessel not occupied by solid substances when it is being charged.

belongs. This seed type became so successful that it is now the standard seed in the cultured quartz industry.

Growth takes place rapidly in the c direction on this seed (easily growing 1 mm/day under good conditions) and less rapidly in the a direction at right angles. The growth in the c direction does not yield a flat face, but rather a surface composed of many rounded small mounds, occasionally showing growth spirals. The c face or basal face $\{0001\}$ is sometimes seen on the tiny crystals studied as micromounts, but it is not a plane.

Growth on a Y-bar seed proceeds in both the c direction and the a direction. Studies have shown that the highest quality is the c direction growth; hence a modified Y-bar is often chosen as a seed, being long in the direction perpendicular to an a axis and of moderate dimensions parallel to the a axis (Figure 2).

Growth in the c direction is highly satisfactory for producing crystals destined for the relatively small AT-cut oscillator plates and various other units, but the need for longer lengths for frequency filters led to the successful use of relatively large seeds oriented parallel to the minor rhombohedral face $\{0111\}$, a cyclic sweep to the early seed (Lias and Rudd 1969). Figure 3 shows representative man-made quartz crystals.

The Q of Quartz

How does one judge the quality of a find of quartz crystal? A material that has a subtle use may require a subtle test of its useful value. The Q of quartz, a dimensionless quotient, is the mark of electronic

Figure 2. Drawing of cultured quartz crystal slightly modified from standard Y-bar, the seed being cut at 85° to the c axis, as shown, instead of 90° to the c axis. The drawing shows elevation and plan views.

Courtesy of Motorola Inc.

Figure 3. Synthetic quartz crystals are produced in a variety of sizes, then cut to specification dependent on final end use requirements.

quality. It often is called mechanical Q . It is highest when energy loss is slowest in a quartz oscillator because of internal friction. Given a resonator vibrating at resonance frequency while connected to a source of alternating current of that frequency, the instant the current is stopped, the vibration amplitude decays. The Q expresses the slowness of the decay. The diminishing sound of a struck bell is a close analogy. A bell with a long tintinnabulation might have a Q of 250,000; a good quartz resonator has a Q of about 1 million.

Practically, the Q of a resonator can be determined as a ratio,

$$Q = 2\pi fL/R,$$

where quantities are measured for the equivalent electrical circuit (a resonating electronic circuit of the same frequency), f being the resonance frequency, L the inductance, and R the resistance (Heising 1946).

A direct method for observing Q displays the decay of the amplitude of a specially made 5-MHz oscillator on the screen of a cathode-ray tube (King 1959). Still another method involves examining the graph of resistance as a function of frequency (Adams, Kusters, and Benjaminson 1968).

The Q of the best natural quartz (measured at room temperature) lies in the range 1.0×10^6 to 3.0×10^6 , and the usual good cultured quartz is about 1/10 of this range. In the early days of quartz-growth study, Q was much lower, and although the crystals

withdrawn from the pressure vessels were clear and sparkling in their beauty, it was discouraging that the artificially produced crystals could not improve on nature.

At Western Electric Co. (a former quartz crystal producer), quartz finally attained a coveted high Q value with the use of lithium nitrite (LiNO_2), as an additive to the growth solution (Ballman, Laudise, and Rudd 1966). Lithium as lithium fluoride (LiF) improved the Q , perhaps by decreasing the infrared absorption at $2.86 \mu\text{m}$ (or the wave number $3,500 \text{ cm}^{-1}$) (King, Ballman, and Laudise 1962). Adding the nitrite raised the Q , at slow growth rate, into the region of natural quartz values. The anion may be adsorbed onto the growing crystal, decreasing the presence of hydroxyl ion in the quartz.

Sawyer Technical Materials LLC developed ways of growing what it labeled Premium Q Cultured Quartz through slow growth in sodium carbonate solution that, in general, yielded a slower rate than sodium hydroxide solutions (Rudd, Houghton, and Carroll 1966; Sawyer 1972). Sawyer tightened quality control on all pertinent aspects of the growth process, gaining a series of runs that produced 5-MHz 5th overtone Q s consistently higher than those yielded by natural quartz.

Compared to glass, quartz has a considerably widened spectral window, hence the use of vitreous silica for optical components and the use of quartz crystal in spectrometer prisms. Quartz, however, shows a number of absorption peaks in the infrared, certain of which have been identified with impurities—elements and radicals. In particular, hydrogen, which is present in great quantity in the hydroxyl ion in alkaline growth solutions as well as in aqueous solutions in the Earth's crust, is known to be responsible for a characteristic high absorption peak in the wave-number region 3,000 to $3,700 \text{ cm}^{-1}$ (Katz 1962).

A relationship was determined experimentally between the infrared absorption at $3,500 \text{ cm}^{-1}$ and the mechanical Q (Cady 1964). Use of this information led Western Electric (Rudd and Liaison 1967) and Sawyer (1972), to inspect their production of crystals for Q by measuring this absorption with an infrared spectrophotometer. This simple and rapid method has made it easier to monitor programs researching improved Q and to ensure quality control.

Defects in Quartz

Quartz destined for piezoelectric oscillators must be reasonably free from various types of defects affecting the crystalline structure. Defects include twinning, structural imperfections such as slip and screw dislocations, impurity ions, and microscopic inclusions. For a review of defects affecting the quality of quartz for electronic and optical use, see Waesche (1960). For a more general mineralogical view, refer to Frondel (1961).

Quartz may show two types of twinning: electrical or Dauphiné twinning and optical or Brazil twinning. These are displayed beautifully under reflected light on slices etched in hydrofluoric acid, a standard method for checking the quality of natural quartz during oscillator manufacture (resonator plates must not show twin boundaries). Twinning is very rarely seen in the seed, which is carefully chosen in cultured quartz.

When pressure vessel, solution, and seeds are heated at the start of the crystal-growing process, the alkaline solution is likely to dissolve holes and tubes along dislocation lines so that when crystal growth begins, these openings are covered and microscopic bubbles (fluid inclusions) result. If the vessel is cooled and opened after the start of the crystal growing process, the seed plates will show etched pits of characteristic shapes suggesting the density of the defects.

Studies using a special double-crystal x-ray spectrometer technique have disclosed much information on structure defects.

The technique produces a topography of the internal structure and assists in relating defects in structure to other defects such as substitutional impurities (Lang 1967).

When considering growth on the basal plane that yields a cobble texture, the basic mechanism of growth seems to be along screw dislocations; this often results in a spiral pattern visible to the eye or under the microscope. Examination by light interference has produced pictures of great interest and beauty (Joshi and Vagh 1964).

Quartz often darkens in certain areas when irradiated with x-rays, high-voltage electrons, or gamma rays from cobalt-60. This phenomenon was traced to the presence of Al^{3+} substituting for some of the Si^{4+} . The charge compensation for the trivalent aluminum generally is provided by Na^+ , H^+ , or Li^+ if the last has been added intentionally as an impurity (Ballman, Laudise, and Rudd 1966). A broad study of hydrogen in quartz has made some of this behavior evident (Katz 1962).

A powerful method of studying a variety of defects such as substitutional, interstitial, and structural defects is to place a quartz block between metal electrodes, heat the assembly, and apply a direct-current voltage for a period of time. Pfenninger (1961) made a detailed study using electrodes of silver, gold, copper, and platinum; voltages as high as 670; and temperatures to 800°C. Methods of observation included using the microscope, the electron microscope, and infrared spectrometry. A beautiful set of photographs shows veils of defects entering quartz, leaving it, and decorating lines of structural dislocations.

Regrettably, this investigation did not include cultured quartz. For preparing quartz, however, especially stable in a radiation environment, cultured blocks are now free from various defects as a result of this general procedure.

A defect occasionally seen—mostly in earlier, less well-controlled growing operations—is microscopic white particles identified as clumps of acmite ($\text{NaFeSi}_2\text{O}_8$) crystals.

Developments in Quartz Growth and Technology

Low Optical Transmission Loss

Cultured quartz has been examined as a material for transmitting infrared laser light of 1.06 μm wavelength (from the neodymium-doped yttrium aluminum garnet [Nd:YAG] laser). Growth in a silver tube to diminish iron contamination yields quartz equivalent in low optical loss to the best commercial vitreous silica (Lias and Rudd 1969). An interesting correlation was found between H^+ concentration in the quartz and the absorption at 1.06 μm : hydrogen ions seemingly provided charge-compensation for the Fe^{2+} or other divalent ion impurities associated with absorption in that region.

Growth Rate on Basal {0001} Plane

Stemming from an eagerness to grow crystals faster (an economic advantage if characteristics can be maintained), growth studies at 374°C and a pressure of about 275.8 MPa led to a rate of about 2.6 mm/day and a Q of about 1.4×10^6 (Lias et al. 1973). The high growth rate caused by higher expected solubility was anticipated; the excellent Q was a bonus and showed that at the higher temperature, H^+ goes less readily into the growing crystal.

Measurement of Viscoelastic Materials

A device used to study the shear modulus of viscous materials employs a delay line of a suitable mechanically rigid material (e.g., vitreous silica or aluminum) mounted on the end a piezoelectric transducer to generate shear waves. This is typically quartz with frequencies in the range of 1 to 7 MHz, but it also may be a piezoelectric ceramic. The delay line is inserted in the sample and the system is brought to constant temperature to within 0.005°C. Pulses

of waves are sent down the delay line and the echoes are measured for their attenuation and phase shift, from which an accurate calculation can be made of the shear modulus (Hunston et al. 1972).

An ultrasonic impedometer can measure the dynamic mechanical properties of viscoelastic materials (adhesives, paints). It employs Y-cut, shear-wave resonators of 5-MHz frequency attached to the ends of a 10-cm bar of vitreous silica. At its ends the bar is cut at 79°, producing a shape suggesting a bathtub. The bulk shear wave is reflected off the bar's top surface where the material to be studied is spread. The reflected wave returns to the transmitting transducer and an oscilloscope displays the amplified signal. The impedance of the film of material can be monitored while the film is drying (Myers and Schultz 1962). Bradfield (1970) gives further general information on ultrasonics.

Pressure Transducer

Because quartz is piezoelectric—that is, a material that produces an electric field as a response to stress—can it be made into a useful pressure gage? A gage having a range of 0 to 69 MPa and an accuracy of about 0.07 kPa is made using a periphery-stressed resonator as a pressure transducer. The transducer unit is a circular 5-MHz resonator whose edge is integral with a surrounding cylinder of quartz, the axis of the cylinder being identical with the normal through the resonator center. The cylinder and resonator are fashioned from a single crystal of quartz using grinding techniques. The resonator can be either an A-T-cut or some other cut to ensure that the temperature coefficient of frequency at zero pressure is zero at a given temperature in the range of 0° to 100°C (Karrer and Leach 1969).

Pressure Gage for High-Impact Conditions

A study, largely performed at Sandia National Laboratories in Albuquerque, New Mexico, produced a gage technique for studying stresses resulting from shock-wave loading of pressures as high as 6×689 MPa (Ingram and Graham 1972). Based on the piezoelectricity of quartz, the device has been used to study the behavior of quartz and other solids under great impact. A valuable use of this technique is the measurement of forces produced in underground nuclear explosions.

Although stresses of 4 GPa are routinely measured, a tungsten facing on the quartz disk extends the upper stress limit of the experiment to 12 GPa. Ordinarily the stress in an oscillating quartz resonator is probably about 600 kPa.

A projectile in a cylinder is faced with a disk of quartz and another disk is provided at the closed end of the cylinder. In this Sandia quartz gage for impact experiments, the cylinder is a 27-m compressed gas gun that can accelerate the projectile to 510 m/sec. The impact velocity can be measured to 0.01%.

Disks of X-cut (the face of the disk perpendicular to an a axis) cultured quartz are used, which can be 126 mm in diameter and 6.3 mm thick—these dimensions yield about one quarter of an ampere of piezoelectric current at a stress of 1 GPa.

During the study of strains up to 4.3×10^{-2} in these experiments, the data analysis revealed unusually accurate values for linear and nonlinear piezoelectric stress constants, and longitudinal elastic constants up to the fourth order (Graham 1972).

Quartz Thermometer

A quartz resonator with resonant frequency unvarying with temperature has not been made, but the behavior with temperature has been thoroughly studied so that, for a given temperature range, a resonator with a reasonably low, and accurately known, variation could be made. Advantage has been taken of this property to measure temperature differences (Smith and Spencer 1963). A 5 Y-cut

(Cady 1964), operating at 5 MHz, has a temperature–frequency coefficient of about 80 ppm/°C and responds to a temperature deviation of 3.8×10^{-6} °C, indicating a very sensitive device.

Commercial development of the quartz thermometer led successfully, through an analysis of plate orientations, to one yielding a linear frequency–temperature relationship. The available instrument has a range of –80° to 250° C with a maximum resolution of 0.0001°C. A digital readout is used, and with optional amplifiers the sensory probe can be as far as 1,372 m from the measuring equipment (Hammond, Adams, and Schmidt 1965).

Quartz Microbalance

A quartz resonator can be brought to a slightly lower frequency by loading it with a little extra mass, say, from evaporated metal. Hence the change in frequency on loading makes the resonator a mass-measuring device. This idea led to the construction of microbalances reading to about 10^{-12} g for certain unusual applications; for example, the measurement of gases that can be adsorbed in a layer of material coating the resonator, such as a hydrophilic substance for weighing water vapor. The frequency change is directly proportional to the change in mass. A 5-mm-diameter, 15-MHz resonator has a mass sensitivity of 2,600 Hz change per microgram. The resonator is usually an AT-cut. The frequency is also a function of temperature. In one method, a zigzag strip of nickel (to serve as heater, thermocouple, and radio-frequency electrode) is evaporated onto one side of the resonator (an AT-cut crystal) (Saubrey 1964; Stockbridge 1966; King 1969).

Surface Waves on Quartz

Elastic solids can display bulk waves or surface waves. Bulk waves are found in quartz oscillators themselves and in buffer rods or other attachments used for conveying a vibration from an oscillator along a length of rigid elastic solid. A use of bulk waves in such a delay line is described in the section on Measurement of Viscoelastic Materials in this chapter. Bulk waves in quartz have also been used to modulate light.

Surface waves—such as the Lord Rayleigh waves that now find standard application in earthquake study—can be produced on various crystalline solids (Viktorov 1968; White 1970). They can be launched in the x direction (i.e., along an a axis) on a quartz bar by means of electric impulses applied to the surface through two evaporated electrodes having the appearance of two interleaved combs or the illustrative diagram of a multiplate capacitor. Similar electrodes at the far end of the bar can receive the waves and convert them into electrical signals. The bar or plate of quartz can be cut parallel to a plane containing an a axis and the c axis—the Y-cut of the piezoelectric engineer. In one application, the bar is 25.4 mm long. The interesting advantage of using elastic waves in certain electronic circuits is the slowness with which they move: about 1.5×10^3 to 15×10^3 m/sec instead of 3×10^8 m/sec, which is the velocity of electric signals and light. Surface waves move in the lower third of that range. A further advantage of surface waves is that they can be sampled or modified. If the y are accompanied by electric or magnetic fields (when they are produced in piezoelectric or magnetic materials), the passage of the wave and its characteristics can be picked up by a sensing device not in contact with the surface.

Another synthetic crystal of much interest in surface wave applications is lithium niobate.

Miscellaneous Uses

Further uses of quartz resonators have appeared in recent years in color television circuits and in watches. The resonator used in a watch design is not the face-shear mode most used for high fre-

quency, 0.5 to 50 MHz, but a flexural, or wave-shaped, mode operating in the range of 2 to 20 kHz (Cady 1964).

MINERALS OTHER THAN QUARTZ

Crystals large enough to hold in the palm of one's hand are of enormous interest because of the astonishing things that they can be made to do. Naturally occurring crystals are not among these, nor are they likely to be; a modern laboratory, however, can create a material with favorable properties through crystal-growing processes that the solid-state physicist can use for electronic, optical, magnetic, or any combination of circuitry.

Few minerals are found with sufficiently high quality to be employed directly. One special exception is calcite; optical calcite is becoming so difficult to find in sizes that are in demand that investigations are under way to synthesize it.

Natural quartz is becoming less important in the frequency-control oscillator industry; mica and selenite are used in very small amounts in making light-retardation plates as microscope accessories.

If a mineral is observed to have a useful property, the crystal grower can probably reproduce it in an improved crystal that is larger, freer of optical flaws, purer, or conversely, doped with impurities (in either case, to give it an effective property).

Synthetic crystals are, in any case, derived from mined ores that undergo various refining and purifying processes—some rather sophisticated—which leads to growing, cutting, and polishing the crystals into usable shapes.

Many of the currently exploited properties of light and crystals have been known since early in the 18th century. Recently, development techniques using intense light beams, high optical quality crystals, or sensitive measuring equipment have been needed to study and apply them. The technology in optical communication is now on the edge of such an expansion as radio and television experienced in the 1940s. The frequency-control resonator, the diode, and the transistor were among those early achievements. Radio frequencies have given way, along the growing front of research, to ultrahigh frequencies close to and within the visible range of the spectrum.

Minerals of Technological Interest

Table 3 is an alphabetical listing of minerals studied earlier, or in current commercial use. Others are not listed, some are only of casual past interest, and some have been overlooked unintentionally. The mineral name is preceded by the Dana identifying number. The chemical formula and the crystal system are given. It should be noted that this is the system for the crystal at ordinary temperature; at lower temperatures a crystal may move into a less symmetric system, and vice versa. Where appropriate, related or replacing crystals are mentioned; the latter have enhanced new and exciting properties.

The useful mineral, property, application, and device are not easily differentiated in every case, depending on the state of the art. Examples follow:

Mineral	Useful Property	Application	Device
Quartz	Piezoelectricity	Frequency control	Oscillator or crystal
Ruby	Fluorescence	Light amplification	Laser

Some of the listed properties are obtained in enhanced value from water-soluble crystals that are not minerals. Whereas halite and sylvite, for example, are minerals soluble in water, the crystal most phenomenal for ferroelectric and piezoelectric use is Rochelle salt, a rather complex and very soluble organic compound. Other

* na = not available.

important synthetic crystals also not found as minerals are germanium and silicon, the single crystal chemical elements used to make diodes, transistors, integrated microcircuits, or computer chips.

Almandine garnet is listed as the precursor of yttrium iron garnet and yttrium aluminum garnet. Perovskite is so listed for the much-valued barium titanate and lead zirconium titanate. Columbite is listed for the family of niobates. Growers and users of optical crystals have been using niobium instead of columbium for the element of atomic number 41.

GLOSSARY

The following list contains some of the terms that apply to the use of minerals and various synthetic crystals in electronic and optical technology. Optics texts are mentioned in the references for further coverage of that limited field.

Absorbance: The value of the expression, $I_n(I_0/I)$, where I_0/I is known as the absorbance and is a numerical statement of the absorption of radiant energy by a transparent material: the ratio of the intensity (W/m^2) of the incident light to the intensity leaving. The constitutive equation is

$$I = I_0 e^{-\alpha d},$$

where α is the absorption coefficient and d is the length of light path in the material.

Acousto-optic: A light-modulating device in which an acoustic wave, ultrasonic in frequency, passing through a suitable crystal plate sets up strained layers with its wave fronts such that an entrant light beam is deflected. Ideally the deflection can be controlled through a critical angle, which can be varied at frequencies into the megahertz range.

Beam splitter: A thin sheet of glass or clear plastic with its surface treated to reflect about half the light incident to it at approximately 45° to the surface. In a more advanced type, two right-angle prisms are cemented along the hypotenuse faces with a material having selected reflection properties to control the ratio of transmitted to reflected light or proportion of color.

Delay line: A device used to delay an electrical signal for a short time, usually milliseconds. In one method, a piezoelectric transducer is mounted on an elongated piece of rigid material, for example, vitreous silica or aluminum. A signal is introduced by the transducer and received on reflection or by another transducer at its far end.

Dielectric: A substance that acts as an electrical insulator, a non-conductor of electricity, or a substance with electric conductivity less than 1×10^{-6} mho. The term may refer to a vacuum and many gases and liquids. Many solid dielectrics, mineral and nonmineral, are opaque or absorb all nonreflected light in a very thin layer. Dielectrics useful in optical technology are transparent in the visible or near-visible range of radiation.

Ferroelectric crystal: A crystal that has the ability to become naturally electrically polarized in a restricted temperature range and exhibits hysteresis between polarization and an applied electric field. If the crystal is heated to the transition temperature (Curie point), the crystal becomes nonpolar. (Piezoelectric crystals become electrically polarized when subjected to a deforming stress.)

Fluorescence: The emission of radiation from a substance that is absorbing radiation of higher energy and shorter wavelength. (There are, however, interesting cases of the [apparent] reverse energy relationship.) Often, large crystal size is not important and powdered fluorescent and luminescent crystals, called *phosphors*, are used in cathode-ray tubes, television kinescopes, and

fluorescent lamps. On the contrary, a large fluorescent crystal bar (i.e., ruby, scheelite, or fluorite), is used in the solid-state laser. Crystals do not have the property of fluorescence if they are strictly pure, and the variation in amount and type of impurity yields useful variations in behavior.

Harmonic generation: The combining of two sets of wave motions having different—but not far removed—frequencies, producing an ongoing wave whose frequency is a multiple or submultiple of the input frequency. Long known in radio technology, this effect in optics uses crystals as the medium in which the action occurs. For further information with only slight mention of minerals, see Schlossberg and Kelley (1972).

Holography: A method of producing whole three-dimensional images of objects by means of recorded light wave patterns, often on photographic film. Holography involves dividing a laser beam (a coherent light source, or one that is of a single wavelength or frequency and with all waves in phase) with a beam splitter so that the continuing beam strikes the film; the reflected beam strikes an object and is reflected back onto the film. The two beams, direct and twice reflected, meet, interfere, and record their interference pattern on the film. A three-dimensional view of the object can be seen on the processed film illuminated by monochromatic light. Remarkable features are that no lens is used; the view is not simply two dimensional; a piece of the film will display the same view as the whole; and a large amount of information is stored on the film. A crystal of lithium niobate has been used as the recording medium.

Laser: A device that emits an intense, narrow beam of coherent, monochromatic light as a result of light amplification by the stimulated emission of radiation (Maiman 1960). Originally the laser comprised a ruby rod energized by an intense source of light nearby; after years of investigations, lasers can now be made of glass, liquid, dye solution, or gas. The light from the ruby, at 6300 \AA , is at the infra-red edge of vision; lasers now produce radiation of both longer and shorter wavelengths. Through modulation at the source and demodulation at a receiving station, the laser can transmit as many as 10^{10} channels, each 10 kHz wide (Nassau 1965; Laudise 1968).

Magneto-optic: In certain crystals through which a beam of polarized light is passing, applying a magnetic field with its lines of force parallel to the beam causes a rotation of the plane of polarization: the Faraday effect. This magneto-optic effect can be used to modulate a light beam.

Modulation: The process and effect of adding information to a radio carrier wave or to a light beam. In radio, AM and FM are well known. A light beam can be modulated by altering its amplitude, frequency, phase, or plane of polarization. The modulation can take a digital form, transmitting simply 0 and 1, or an analog form that includes voice and music. The amplitude (or intensity) of a light beam can be modulated, for example, by applying a varying electric field to an electro-optic crystal carrying the beam. The crystal is sandwiched between crossed polarizers to provide the rest of the optical requirement.

Nonlinear: Behavior that does not follow a straight line or proportionality relationship when one variable is altered and a dependent variable is observed. In electronics, for example, the behavior of current through a diode with respect to applied voltage is nonlinear. The optical properties of a medium are linear when the intensity of the transmitted light is low, as is normally the case. Nonlinear refers to changes in the optical properties as the intensity of transmitted light is greatly increased, or when two or more strong light beams are combined in the medium. The study of nonlinear phenomena is the basis of progress in

electronic and optical technology: solar power, transistor, laser, and holography (Schlossberg and Kelley 1972).

Piezoelectric effect: An electric reaction or charge resulting from applying a physical stress (compression, bending, or twisting) to a substance (element, crystal, etc.). The converse effect also applies—the element tends to deform when an electric field or charge is applied. Actual motion or strain is usually involved. The substance, commonly a macrocrystal, can be an assemblage of microcrystals as in a piezoelectric ceramic. That the crystal has no center of symmetry is a necessary crystallographic condition. Applications have included frequency-control resonators of quartz and phonograph pickups of Rochelle salt (not a mineral) and of lead zirconium titanate (related to perovskite).

Property: Relates to any of the principal characteristics of a substance, especially as determined by the senses but also determined by any variety of sophisticated sensing equipment, for example, infrared transparency, laser capability, or semiconduction.

Pyroelectric: The property of a crystal such that electric charges appear on certain faces when it is heated or cooled. Strontium niobate, a synthetic crystal related to columbite, shows such a strong effect that it can serve as a practical infrared detector.

Q-switch, or Q-spoiler: A fast-acting light valve used with lasers to arbitrarily hold back light emission and let it burst forth at the flick of the switch in a high-energy flash. Electro-optic crystals and the Kerr cell using nitrobenzene and a high-voltage pulse have been used for such shutters and require the presence of polarizers on each side in a crossed position. Acousto-optic crystals and solutions of certain dyes also are used.

Resonator: A device or system in which a characteristic vibration can occur involving a continuous exchange between potential and kinetic energy. Examples follow:

- A *piezoelectric resonator* is a rectangular plate (sometimes a disk or bar) of piezoelectric material, commonly quartz, that will vibrate characteristically when placed in an alternating voltage field that has the same frequency as the natural mechanical frequency of the plate. The motion can assume various types or modes: compression, shear, or flexural. Piezoelectric resonators of quartz for frequency control cover the range of about 1 kHz to 55 MHz. A piezoelectric plate can be driven at frequencies different from the resonance frequency.
- An example of an *acoustic energy cavity resonator* is the organ pipe. In microwave technology, a resonator is a metal box or cavity in which electromagnetic energy can be stored; the resonance frequency is determined by the geometry of the enclosure.
- An example of an *optical resonator* is the Fabry-Perot resonator or interferometer; two parallel, partially reflecting mirrors cause the light entering in one direction to oscillate before exiting. In a common application, light is passed through a converging lens to form an interference figure of highly contrasting fringes on a screen. The laser may be called a Fabry-Perot resonator.

Acid Neutralization

Ben Koopman

INTRODUCTION

Because extreme pH values in water are harmful to humans and aquatic life, the pH of drinking waters and treated wastewater effluents is regulated. Extreme pH is also corrosive to water piping systems. The allowable pH range of wastewater effluents that are discharged to receiving waters is typically 6 to 9 or 6.5 to 9.

Reagents used for neutralizing acids are derived from chemical processes such as the electrolysis of brine to produce caustic soda and from minerals such as limestone, which can be used directly for neutralization or can be processed into various forms of lime. Alkaline industrial wastes and metallic iron are also important reagents.

Some of the reagents employed for acid neutralization are also used to remove acid-forming components from flue gases, to purify and soften water, and to pasteurize wastewater sludge. The quantities involved are significant to the minerals industries. For example, almost 1.0 Mt of lime were used in treating water for municipal and industrial supplies in 2001 (National Lime Association, undated [a]). In fact, lime is the most-used chemical in the water treatment industry.

This chapter first describes the commonly used acid neutralization reagents, including chemical nature and primary routes of production, and also mentions some waste-derived materials that

have shown promise. Production and consumption statistics are discussed and trends are noted, and properties and prices of the commonly used reagents are compared. The major environmental applications of these materials are then described.

ACID NEUTRALIZATION REAGENTS

The most common reagents for neutralization are caustic soda and various forms of lime. Other chemicals with important uses include soda ash, magnesium hydroxide, and anhydrous ammonia. Some waste materials, notably the combustion products of coal, have also been suggested as materials for neutralization. Because the common or commercial names for many of the reagents differ from their chemical names, a list of the reagents is presented in Table 1. Representative chemical formulas are also given in the table. Commercial reagent formulations may vary from the pure chemical formula.

Limestone

The term *limestone* has been widely applied to mean rock that is principally composed of calcium carbonate. Many limestones were formed 100 to 500 million years ago from compressed layers of calcareous marine deposits. Other types of limestone include chalk, which is a soft sedimentary deposit of marine calcareous fossils, and marble, which is hard metamorphic rock formed from

Table 1. Common names, chemical names, and representative chemical formulas of acid neutralization reagents

Common name	Representative Chemical Formula	Chemical Name	Other Common Names
Ammonia	NH ₃	Ammonia	Anhydrous ammonia
Caustic soda	NaOH	Sodium hydroxide	
Dolomitic limestone	CaCO ₃ •MgCO ₃	Calcium carbonate/magnesium carbonate	
Dolomitic quicklime	CaO•MgO	Calcium oxide/magnesium oxide	
Half-burnt dolomite	CaCO ₃ •MgO	Calcium carbonate/magnesium oxide	
High-calcium hydrated lime	Ca(OH) ₂	Calcium hydroxide	Slaked lime
High-calcium quicklime	CaO	Calcium oxide	Burnt lime, oxide lime
High-calcium limestone	CaCO ₃	Calcium carbonate	
Magnesia	MgO	Magnesium oxide	
Magnesium hydroxide	Mg(OH) ₂		
Normal dolomitic hydrated lime	Ca(OH) ₂ •MgO	Calcium hydroxide/magnesium oxide	Dolomitic hydrate type N
Pressure dolomitic hydrated lime	Ca(OH) ₂ •Mg(OH) ₂	Calcium hydroxide/magnesium hydroxide	Dolomitic hydrate type S
Soda ash	Na ₂ CO ₃	Sodium carbonate	

sedimentary material. Calcite is the predominant crystalline form of calcium carbonate found in lime stones. Sedimentary deposits of recent origin may contain aragonite, a metastable crystalline form that is gradually converted to calcite over geological time.

Dolomitic and Magnesium Limestones

Some limestone deposits contain both calcium and magnesium carbonates. The mineral dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$) contains equimolar amounts of calcium carbonate and magnesium carbonate. The chemical composition of dolomite by weight is 54% calcium carbonate and 46% magnesium carbonate. According to the National Lime Association, the term *dolomitic limestone* is applied to limestones containing more than 35% magnesium carbonate. Limestones with intermediate contents of magnesium carbonate (5% to 35%) are classified as magnesium limestones.

High-Calcium Limestone

Limestone with a high content of calcium carbonate (and thus a low content of magnesium carbonate) is referred to as high-calcium limestone. The magnesium carbonate for this classification is 5% or less.

Production and Use

In 2002, 978 Mt of limestone and 97 Mt of dolomite were produced in the United States. The leading states for limestone production were Texas, Florida, Missouri, Ohio, and Pennsylvania; their combined production was 40% of the total. Illinois, New York, Pennsylvania, Ohio, and Indiana led in production of dolomite, together producing 65% of the U.S. total. Removal of sulfur dioxide (SO_2) from flue gases consumed 3.0 Mt of limestone. Another 0.17 Mt were used for mine dusting or acid water treatment (Tepordei et al. 2002).

Over the 5-year period from 1998 through 2002, the yearly U.S. production of limestone and dolomite was relatively flat. Use of limestone for sulfur dioxide removal almost doubled during the period, starting at 1.7 Mt and ending at 3.0 Mt. In contrast, application of limestone in mine dusting or acid water neutralization exhibited a slight decreasing trend. A continuing trend toward more stringent U.S. Environmental Protection Agency (EPA) limitations on SO_2 emissions should provide growth opportunities in the limestone flue gas desulfurization (FGD) market.

Lime

Both calcium oxide and calcium hydroxide are commonly referred to as lime. These compounds are also distinguished by the terms *quicklime* and *hydrated lime*, respectively. Other terms for quicklime are *burnt lime* and *burnt limestone*.

Quicklime

Quicklime is manufactured by heating (calcining) limestone at temperatures in the range of 900 °C to 1,300 °C (Moropoulou, Bakolas, and Aggelakopoulou 2001; Georgallias et al. 2002) to drive off carbon dioxide (CO_2), leaving calcium oxide, as shown in Equation (1).

Quicklime is classified chemically according to the calcium carbonate content of the limestone from which it is made. High-calcium quicklime is derived from high-calcium limestone, magnesium quicklime from magnesium limestone, and dolomitic quicklime from dolomitic limestone.

Because the heat of decomposition of CaCO_3 is higher than that of MgCO_3 , the temperature required to drive off the CO_2 from calcium carbonate is also sufficient to drive off the CO_2 from magnesium carbonate. Calcining dolomitic limestone at this temperature yields a product that contains only the oxides of calcium and magnesium— $\text{CaO} \cdot \text{MgO}$. This reagent is referred to as dolomitic quicklime. Calcining dolomitic limestone at a somewhat lower temperature drives off only the CO_2 associated with magnesium, producing a mixture of calcium carbonate and magnesium oxide (e.g., $\text{CaCO}_3 \cdot \text{MgO}$). This reagent is referred to as half-burnt dolomite.

Hydrated Lime

Hydrated lime is a dry powder produced by reacting quicklime with sufficient water to form calcium hydroxide, Ca(OH)_2 , as shown in Equation (2).

It is worth noting that the reaction is exothermic and should be carried out with equipment that can safely conduct away the released heat energy.

The chemical composition of hydrated lime depends on the composition of the quicklime from which it is made, the hydrating conditions, and the quantity of water used. High-calcium hydrated lime is produced from high-calcium quicklime and generally contains between 72% and 74% calcium oxide and 26% to 28% chemically bound water.

When hydrated under normal (atmospheric) conditions, only the calcium oxide fraction of dolomitic quicklime reacts with water:

The normal dolomitic hydrated lime resulting from Equation (3) is composed of 49% calcium oxide, 35% magnesium oxide, and 16% chemically bound water by weight. Commercial grades of dolomitic hydrated lime will vary in composition.

Hydrating dolomitic quicklime under pressure (and elevated temperature) causes all of the magnesium carbonate, as well as the calcium carbonate, to react with water, as shown in Equation (4).

The pressure dolomitic hydrated lime resulting from Equation (4) contains 43% calcium oxide, 30% magnesium oxide, and 27% chemically bound water by weight. Commercial grades of pressure dolomitic hydrated lime will vary in composition.

Production and Use

U.S. production of lime in 2003 was 19 Mt, compared to an estimated worldwide total of 120 Mt (Miller, Miller, and Wallace 2003). The largest producers were China (23 Mt), the United States, Russia (8 Mt), Japan (7.5 Mt), and Germany (7 Mt). The amount of lime consumed for environmental applications in the United States in 2003 was 5.3 Mt. Most of this was for FGD (65%), followed by drinking water treatment (17%), wastewater treatment (7%), sludge treatment (6%), acid mine drainage mitigation (2%), and miscellaneous applications (2%).

Worldwide lime production has generally trended upward in the past 5 years, increasing from 116 to 120 Mt during this period. U.S. production and consumption rates for environmental applications, however, have been relatively flat. EPA's new interstate air quality rule requires that deep cuts in SO_2 emissions be achieved in

the coming decade. More FGD scrubbers must be installed to comply with the rule, but the implementation schedule could be stretched out as electrical utilities cash in allowance credits banked under the Acid Rain Phase II Program (Miller, Miller, and Wallace 2003). Besides the interstate air quality rule, the acid rain program already in place, incinerator regulations, and upcoming EPA standards for control of industrial hazardous air pollutants are providing growth opportunities in lime's FGD market.

Caustic Soda

Caustic soda (NaOH) is formed along with chlorine from the electrolysis of brine solution. The most common commercial grade is 50% NaOH by weight. Solution of this strength begins to freeze at temperatures below 18°C, so some users prefer more dilute concentrations that freeze at lower temperatures. For example, 20% NaOH freezes at around -10°C (Jones-Hamilton Co. 2004).

In 2001, the U.S. demand for caustic soda was 11 Mt (Kirschner 2003), compared to a global demand of 46 Mt (Shamel and Udis-Kessler 2001). Consumption of caustic soda for water treatment is about 5% of the U.S. demand. The trend in U.S. demand was downward in the 5-year period from 1998 through 2002.

Soda Ash and Sodium Hydrogen Carbonate

Soda ash (sodium carbonate) and sodium hydrogen carbonate (sodium bicarbonate) are produced by refining the minerals trona ($\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot \text{H}_2\text{O}$) and nahcolite (NaHCO_3) or sodium-carbonate bearing brines (Kostick, Milanovich, and Coleman 2003). Soda ash can also be produced synthetically by one of several chemical methods. One of these is the Solvay process, which uses limestone, salt, and ammonia as the raw materials. Disadvantages of synthetic soda ash are its higher cost of production and environmentally deleterious wastes.

The United States and China are the largest producers of soda ash, together accounting for more than half of worldwide production in 2003. Applications of soda ash for FGD and water treatment were equal to 1.2% and 0.7%, respectively, of the 2003 U.S. production of 19 Mt (Kostick, Milanovich, and Coleman 2003).

The trends in soda ash production from 1999 through 2003 were consistently positive in both the United States and around the world. In contrast, soda ash consumption for water treatment during the same period was relatively flat, and consumption for FGD exhibited a downward trend.

Magnesia and Magnesium Hydroxide

Naturally occurring materials such as magnesite (magnesium carbonate), brucite, dolomite, olivine, brines rich in magnesium chloride, and seawater are used to produce magnesia (magnesium oxide). Conversion of magnesium carbonate to magnesium oxide is accomplished through heating (calcination), which liberates CO_2 :

The temperature of the calcining process influences the properties of the magnesium oxide product. A temperature from 700°C to 1,000°C yields a high-surface-area, reactive material known as light-burned or caustic-calcined magnesium oxide. This is the product that is useful in acid neutralization. Higher calcination temperatures yield materials with lower surface areas and, hence, lower reactivities. Water can be added to produce the hydrate (magnesium hydroxide).

The conversion process for brines or seawater rich in magnesium chloride typically involves adding lime or dolomitic quicklime. The ensuing reaction forms magnesium hydroxide particles in

a solution of calcium chloride. When dolomitic quicklime is added, the reaction is (Martin Marietta Materials 2003)

The magnesium hydroxide particles are collected by gravity sedimentation and washed to remove residual calcium chloride. The magnesium hydroxide can be calcined to produce magnesium oxide.

The U.S. consumption of caustic-calcined magnesia in 2003 was 30,000 t, compared to a production level of 154,000 t (Kramer, Inestroza, and Wallace 2003). Net imports, mostly from China, thus satisfied almost half of the U.S. demand. Water treatment and stack gas scrubbing together accounted for 45% of the caustic-calcined magnesia consumption in the United States. Domestic production of magnesium hydroxide was 217 kt in 2003, slightly greater than the demand of 209 kt. Most of this chemical was used in water treatment.

The trend in U.S. production of caustic calcined magnesia was generally downward from 1999 through 2003, corresponding with expansion of magnesia processing capacity in China. A sharp upturn occurred between 2002 and 2003, however, corresponding to increased environmental applications. The trend of U.S. magnesium hydroxide production from 1999 through 2003 was relatively flat. Use of magnesia and magnesium hydroxide in water treatment is growing as these compounds are increasingly accepted as alternatives to caustic soda. More stringent air pollution regulations should lead to expansion of applications for stack gas scrubbing. As a result, an increasing trend in environmental applications should be expected in the future.

Ammonia

Ammonia (NH_3) is a neutral alkaline, colorless chemical that dissolves readily in water, forming ammonium hydroxide. Steam reforming of natural gas or other light hydrocarbons is the most important process for synthesis of anhydrous ammonia, accounting for 85% of ammonia production worldwide (Appl 1999). Additional ammonia is produced by partial oxidation of heavy fuel or vacuum residue. About 77% of world ammonia capacity is currently based on natural gas, with this feedstock expected to remain dominant over the next half century (EFMA 2000).

World production of ammonia is estimated at 100 Mt yearly, with U.S. production pegged at 14 to 16 Mt yearly (Fee 2003). Most (80%) of the manufactured ammonia is used in agriculture. Of the remaining 20%, wastewater neutralization is the fifth most important application.

Novel Materials

Novel materials for neutralization include alkaline waste materials from industrial processes and zero-valent iron. Industrial wastes that contain high contents of alkaline chemicals can be reacted with acids in a acidic waste streams to accomplish neutralization, thus functioning in similar fashion to the conventional acid neutralization reagents. Zero-valent iron promotes alkalinity-forming redox reactions in the environment.

Alkaline Industrial Wastes

Alkaline wastes considered for acid neutralization include coal combustion by-products (CCBs), steelmaking slag residues, and sludge from bauxite processing via the Bayer process (known as *red mud*). Some 100 Mt of CCBs are generated annually in the United States, of which 25 Mtpy are applied for such beneficial uses as concrete products, structural fill, waste stabilization, and road grade construction. The remaining 75% must be disposed of,

with landfills being the most likely repository (EPA 2000). Types of CCBs include fly ash, bottom ash, fluidized bed ash, boiler slag, FGD ash, and others. These different residues differ in their physicochemical properties. CCBs with high alkaline contents and low exchangeable toxic constituents are suitable for neutralization of acid wastes (Canty and Everett 2001).

Slags from the basic oxygen steelmaking (BOS) process contain large amounts of lime and calcium silicates (Ca_2SiO_4 and Ca_3SiO_3). The alkaline nature of these materials makes such slags possible candidates for acid waste neutralization (Bodurtha and Brassard 2000). Limited amounts of BOS slags are currently used as liming agents in agriculture and as soil conditioners (Lopez et al. 1995).

Red mud is a fine-textured residue from bauxite refining that is currently dumped in holding ponds, which require large areas of land. The principal components of red mud are oxides of iron (Fe), aluminum (Al), and titanium (Ti), which give it high surface reactivity. The liquid phase is primarily a weak solution of sodium aluminate. Its texture and composition confer a high surface reactivity on red mud. It has a high pH (typically 10), is highly alkaline, and forms stable suspensions in water (Altundogan and Tumen 2003; Hanahan et al. 2004).

The potential of alkaline waste materials for acid waste neutralization is accompanied by concerns about the variability in their composition and the contaminants they may contain, particularly heavy metals. Thus, waste-derived acid neutralization agents should be thoroughly characterized as part of the decision-making process in evaluating specific applications.

Zero-Valent Iron

Finely divided metallic iron or, more simply, ground-up scrap iron, has been demonstrated for treatment of halogenated hydrocarbons and heavy metals in groundwater (Matheson and Tratnyek 1994; Shokes and Möller 1999). Iron also exerts a neutralizing effect by promoting chemical and biochemical reduction reactions (e.g., conversion of sulfate to sulfide) that produce alkaline compounds as a by-product (Wilkin and McNeil 2003). Zero-valent iron is attractive because it reacts relatively quickly, has high reduction potential, is nontoxic, and can be obtained from scrap.

ENVIRONMENTAL APPLICATIONS

Acid neutralizing reagents are widely used in the treatment of water for municipal and industrial supplies, purification of municipal and industrial wastewaters, and remediation of acid mine drainage. Significant quantities are also used for the stabilization and dewatering of municipal biosolids and industrial sludges and for FGD. These applications are described in the following sections.

Neutralization of Acidic Wastewaters

The most popular reagents for neutralization of acidic wastewaters are caustic soda and various forms of lime. Ammonium hydroxide is occasionally used for neutralization of industrial wastewaters, and magnesium hydroxide has received attention (Hairston 1996). Factors that should be considered in choosing the optimal reagent include cost, neutralization capacity, reaction rate, storage and feed rate, and neutralization products.

Cost and Basicity

Selected acid neutralization reagents are compared in Table 2 in terms of cost, basicity, and cost per metric ton of basicity. Magnesia is the most expensive reagent, followed by ammonia, caustic soda, soda ash, hydrated lime, quicklime, and limestone. The basicity of the reagents also varies. Basicity is a measure of the alkali available

Table 2. Cost and basicity of selected acid neutralization reagents

Reagent	Price, \$/dry t	Basicity,* metric tons equivalent CaO per metric ton dry reagent	Cost, \$/t basicity
Caustic soda	317 [†]	0.69	459
Magnesia	538 [‡]	1.31	412
Soda ash	169 [†]	0.51	331
Ammonia	411 [§]	1.65 ^{**}	249
Hydrated lime	102 [†]	0.71	144
Quicklime	61 [†]	0.94	65
Limestone	12 ^{††}	0.49	24

* Basicity as reported by Hoak (1950).

[†] 2003 cost from *Chemical Market Reporter* (2003) for truck or railroad-car quantities.

[‡] 2003 cost from Kramer, Inestroza, and Wallace 2003.

[§] 2003 cost from Fee (2003).

^{**} Calculated basicity, metric tons equivalent CaO per metric ton anhydrous reagent.

^{††} 2002 cost from Tepordei et al. (2002) for crushed stone applied in mine dusting or acid water treatment.

for neutralization, relative to pure calcium oxide. This parameter ranges from 1.65 for ammonia to 0.49 for limestone. Caustic soda has a relatively low basicity (0.69) compared to magnesia (1.31) and ammonia (1.65) and thus is the most expensive reagent on a cost per metric ton of basicity basis. The least expensive reagent, both in terms of chemical cost and cost per metric ton of basicity is limestone.

Price volatility is also a factor to consider in reagent selection. As Figure 1 shows, prices for soda ash and magnesium hydroxide powder were very stable from 1999 to 2003, whereas high-calcium quicklime and limestone showed slight increasing trends. Each of these reagents is derived from abundant mineral deposits, which helps to explain their price stability. In contrast, anhydrous ammonia and caustic soda prices have experienced severe volatility. Because ammonia synthesis is highly energy intensive, price swings in this commodity directly reflect energy prices, particularly that of natural gas, which is one of the primary raw materials for ammonia synthesis. Prices of caustic soda tend to mirror those of chlorine, its co-product. Large-magnitude fluctuations in worldwide demand for chlorine in organic chemical synthesis thus lead to wide swings in the price of caustic soda.

Reaction Time, Maximum pH, Sludge Characteristics, and Effect on Total Dissolved Solids

Caustic soda, soda ash, and lime are compared in Table 3 in terms of reaction time, maximum pH, sludge characteristics, and effect on total dissolved solids. Caustic soda reacts almost instantaneously with acids; soda ash and lime are somewhat slower acting. The maximum pH (at 25°C) that could be obtained by adding caustic soda to water is 14, compared to 12.4 with lime and around 11 with soda ash. Sludges produced by neutralization with caustic soda or soda ash tend to be voluminous and difficult to dewater if heavy metals are present. Lime neutralization produces a lower volume, denser sludge that has better dewatering characteristics, even with heavy metals present. Both caustic soda and soda ash produce soluble end products, increasing the total dissolved solids of the treated effluent. Lime produces insoluble calcium salts and can thus decrease the effluent total dissolved solids.

Despite being relatively expensive, caustic soda is widely used because of its uniformity, ease of storage and feeding, rapid reaction rate, and solubility of end products. Soda ash is less reactive than

Figure 1. Relative prices of selected acid neutralization reagents between 1999 and 2003

Table 3. Comparison of common neutralization reagents

Reagent	Maximum pH at 25°C	Relative Reaction Rate	Sludge Characteristics	Nature of Salts Produced
Caustic soda	14	Nearly instantaneous	High volume; gel-like if heavy metals present	Soluble sodium salts
Soda ash	>11	Moderately fast acting	High volume; gel-like if heavy metals present	Soluble sodium salts
Quicklime or hydrated lime	12.4	Moderately fast acting	Dense, low volume; good dewaterability, even if heavy metals present	Insoluble calcium salts

Adapted from National Lime Association 2000.

caustic soda and can produce frothing problems caused by the release of CO₂. Quicklime and hydrated lime are attractive because they are low in cost but still possess moderately high reactivity. Handling of these particulate solids is complex, however. Dry lime tends to bulk and bridge in storage, so equipment such as agitators must be installed on silos to ensure reliable delivery. Quicklime must be hydrated on-site, using slaking equipment, before feeding to the neutralization reactor. Lanouette (1977) suggested that hydrated lime could be fed directly from storage to the neutralization reactor, whereas Conway and Ross (1980) recommended that it be fed as a slurry with 15% contained CaO. Slurry feeding of hydrated lime increases reaction rate because the time required for dissolution of reagent in the reactor is eliminated.

Table 4. Reagent requirements for neutralization of waste acids

Reagent	Kilograms Required per 100 kg Waste Acid		
	H ₂ SO ₄	HCl	HNO ₃
Liquid caustic soda (50% NaOH)	164	220	127
Soda ash	119	160	93
High-calcium limestone	110	148	86
Dolomitic limestone	94	127	73
High-calcium hydrated lime	79	107	62
Dolomitic hydrated lime	65	87	51
High-calcium quicklime	60	80	46
Dolomitic quicklime	54	73	42

Adapted from Patterson 1985.

Limestone is most economical in terms of reagent cost, but it has the least reactivity. Pulverizing limestone increases its reaction rate but approximately doubles the reagent cost (Conway and Ross 1980). Limestone-packed beds have proven to be a feasible approach to low-cost neutralization. They are capable of achieving effluent pH 5.0 to 6.5 at appropriate hydraulic loading rates (Bisogni and Vaillancourt 1980). Reaction of limestone with acidic wastewater produces bicarbonates and CO₂. Aeration of limestone reactors or packed beds may be needed to strip out CO₂ so that effluent pH can be raised above 4.3 (Krylenko 1976; Oh sawa 1976). The bicarbonates exert a buffering effect that is capable of achieving near-neutral effluent pH without automatic pH control systems (Pilot 1974). Head loss through packed bed reactors is a major design consideration. Operation of limestone beds in upflow mode has been recommended to flush out fine suspended matter that could blind the bed, as well as to flush out CO₂ (Mezey 1979).

Substantial quantities of sludge can be produced when lime is employed to neutralize sulfuric acid wastes. This results from the formation of insoluble calcium sulfate (gypsum). Use of dolomitic lime can ameliorate this problem, because of the increased solubility of magnesium sulfate relative to calcium sulfate. Because dolomitic limes are less reactive than high-calcium limes, longer reaction times would be required for their application. Neutralization of sulfuric acid wastes with limestone beds can lead to formation of gypsum scale on limestone particle surfaces, reducing the rate of neutralization and increasing head loss. An acid concentration of 5% and surface loading of 12 m per hr were given as upper loading limits for limestone beds treating sulfuric acid waste (Nemerow and Dasgupta 1991).

Reagent Quantities

Quantities of reagent required for the neutralization of sulfuric acid, hydrochloric acid, and nitric acid wastes are shown in Table 4. Use of liquid caustic soda (50% NaOH) requires the most reagent, followed by soda ash, limestone, hydrated limes, and quicklimes. Dolomitic limestone, hydrated lime, and quicklime require somewhat less reagent than the corresponding high-calcium forms because of the lighter atomic weight of magnesium in comparison to calcium.

Ferrous iron salts in acidic wastewaters tend to be oxidized and then form hydroxide precipitates when the pH is raised, for example:

As shown in Equation (8), precipitation of ferric hydroxide consumes alkalinity from the water. Consequently, neutralization of wastewaters from metal plating and ferrous industries can consume several times the amount of base that would be required to neutralize similar wastewaters not containing iron salts (Mac Dougall 1954; Anon. 1968).

Several alkaline wastes have been considered for neutralization of acidic wastewaters. Polat et al. (2002) evaluated coal fly ash as a neutralization/fixation agent for used engine oils. They noted that trace elements and organic components were efficiently fixed within fly ash particles. The neutralization capacity of steelmaking slag residues was examined by batch titration with sulfuric acid (Bodurtha and Brassard 2000). Neutralization profiles revealed two-phased kinetics, in which the free lime, magnesium and silicon oxides, and dicalcium ferrite dissolved almost completely within a few days, whereas weakly bound lime and magnesium oxides dissolved over a period of 10 to 80 days. Although the slag possessed the same neutralizing capacity as limestone, its slow dissolution kinetics and high cost of crushing decrease its attractiveness.

Neutralization of Acid Mine Drainage

The drainage from mines is often rich in sulfide minerals, which are oxidized on exposure to air. Acid resulting from the oxidation can lower the pH of the drainage waters to 2.0 or less (Mill 1972). In addition to high acidity, acid mine drainage typically contains high concentrations of sulfate, suspended solids, and heavy metals. These components are harmful to aquatic life and must be eliminated before drainage waters are released to the environment (Kuyucak 1998). Reagents and processes used for treatment of acid mine drainage are discussed in the following sections.

Lime

Neutralization with lime is widely used for treatment of acid mine drainage. This technology effectively decreases dissolved heavy metal concentrations to below regulated limits. Large quantities of sludge are produced, resulting from the precipitation of calcium sulfate and metal hydroxides and the removal of suspended solids. The sludges tend to have poor dewatering characteristics and often contain less than 5% solids by weight (Zinck and Aube 2000).

Limestone

A denser sludge is obtained with limestone, but this reagent is not effective above pH 6.5 because of its slow reactivity at pH values approaching neutrality. Cox (1998) evaluated the effectiveness of in situ limestone treatment of acid mine drainage. The buffering potential increased as aggregate size decreased, but decreased on repeat exposure to drainage. Cox concluded that limestone aggregate may be a control measure for acid mine drainage produced in spoil piles, tailing ponds, and other surficial settings. Ziemkiewicz et al. (1997) evaluated open limestone channels as a low-maintenance system for acid mine drainage. They found that limestone, after being coated with metal hydroxides (armored), was up to 90% as effective in neutralizing hydrochloric acid solution as unarmored limestone. Limestone channels were considered promising for watershed restoration projects and abandoned mine land reclamation projects that do not have to meet specific water quality goals. Anoxic limestone drains have been used for increasing the alkalinity of groundwater affected by acid mine drainage (Kuyucak 1998). Plastic and clay-soil covers are used to exclude air from seepage interception trenches that have been backfilled with crushed limestone. Because armoring of limestone is associated with oxidation of Fe^{2+} and formation of ferric oxyhydroxides, exclusion of air from limestone drains should improve their effectiveness and

extend their life. Precipitation of iron and other contaminants is usually achieved in a downstream wetland.

Ammonia

Anhydrous ammonia (NH_3) is a gas at ambient temperatures and is compressed and stored as a liquid. It dissolves readily when released into water, behaving as a strong base with peak buffering capacity at pH 9.2. Because of its high reactivity, ammonia may be considered as an alternative to caustic soda (Skousen et al. 1998). Several disadvantages are attendant to the use of ammonia, however. First, it is a hazardous material to handle. Second, because ammonia is toxic to aquatic biota, downstream concentrations must be carefully monitored. Third, oxidation of ammonia to nitrate produces acid and thus can cause pH problems downstream of the injection point. Finally, ammonia is a plant nutrient, both in its original form or as nitrate, and can promote eutrophication in downstream reservoirs or lakes or, ultimately, in the coastal ocean.

Biological Processes

Biological processes for treatment of acid mine drainage depend largely on sulfate-reducing bacteria to produce sulfides that precipitate heavy metals. Net consumption of protons in the reduction reactions tends to raise pH, leading to further precipitation of heavy metal oxyhydroxides and improving the bacterial growth environment. Organic matter required by the sulfate-reducing bacteria is provided by the decay of aquatic plants growing in the wetlands. Additional organic materials (e.g., straw, sawdust, wood shavings, and manure) may be added to supply nutrients to the bacteria, as well as supplemental organic matter (Kuyucak 1998). Passive reactive barriers for treatment of acid mine drainage may depend wholly or partially on sulfate-reducing bacteria. The key parameters of biological systems for treatment of acid mine drainage include temperature, availability of organic matter, loading, and pH. Biological activity depends strongly on temperature; for this reason, the design loading of these systems must take the local climate and seasonal temperature variations into account.

Alkaline Industrial Wastes

Co-mingling of cement kiln dust and red mud with acid-generating tailings was evaluated by Duchesne and Doye (2003). Static and column tests showed that near-neutral conditions were maintained in the fine material layers of mixtures containing 5% or 10% cement kiln dust or 10% of a combination of the two wastes. This significantly decreased concentrations of Al, Fe, Cu, Zn, and SO_4 relative to tailings only. Numbers of viable sulfide-oxidizing bacteria were also decreased.

Coal Combustion By-products

CCBs from processes that add lime or limestone for SO_2 control are good candidates for neutralization of acid mine drainage or mining wastes. Canty and Everett (2001) evaluated the suitability of CCBs for alkaline injection technology. FGD ash and fluidized bed ash had the highest contents of available alkalinity, whereas pulverized coal burner fly ash contained substantially less alkalinity. Toxic heavy metals were associated with all the CCBs. They were most difficult to leach from fluidized bed ash and least difficult to leach from the fly ash. Pozzolanic character is undesirable because it leads to formation of cementitious masses. Fluidized bed ash had the lowest pozzolanic character; fly ash had the highest. Thus, fluidized bed ash was considered most suitable for mine injection. Vondruska, Bednarik, and Sild (2001) used fluidized bed ash for the stabilization/solidification of ferrous sulfate waste generated from production of titanium dioxide. The pH of the waste was initially 1.9. After

mixing equal portions of waste and fluidized bed ash, the pH was raised to 6.5. Heavy metal concentrations in leachate from mixtures that were allowed to harden for 28 days were below detection limits. Zoumis, Calmano, and Förstner (2000) compared the neutralization and heavy metal removal capacity of fly ash, red mud, zeolite, calcium-bentonite, scale arrears, and pine bark. Fly ash and red mud had the highest acid neutralization capacities and gave the best heavy metal removals.

Zero-Valent Iron

Metallic (zero-valent) iron is a reducing agent relative to many redox-labile substances, including hydrogen ions, carbonate, sulfate, nitrate, and oxygen. Metallic anions and cations are reduced by iron in the absence of oxygen (Blowes et al. 2000). Net proton consumption is associated with the redox reactions. Wilkin and McNeil (2003) exposed heavy metal ions from salts of As(V), Ni, Cd, Cu(II), Hg(II), Mn (IV), and Zn to finely divided iron metal under oxygen-free conditions. They noted that the pH of synthetic acid mine drainage containing the heavy metal ions and zero-valent iron increased from initial values of 2.3–4.5 to final values of 5.5–10.0 in the first 24 hours of reaction. Between 1.4 and 225 $\mu\text{mol H}^+/\text{L}$ was consumed. Significant decreases in heavy metal concentrations, with the exception of Mn, paralleled acid neutralization. Remobilization of metals, if it occurred, was associated with exhaustion of acid-neutralization capacity of the iron. Monitoring data from a demonstration-scale permeable reactive barrier containing zero-valent iron showed that the pH of groundwater underwent a sharp increase in pH, from 5.5–6.5 to 9.5–11.0, when flowing through the barrier (Blowes et al. 2000). This was paralleled by an 8 mg per L decrease in Cr(VI) and a 15 to 120 mg per L decrease in SO_4 . The relative magnitudes of these concentration changes suggest that most of the proton consumption resulted from SO_4 reduction (Mayer 1999). Shokes and Möller (1999) noted that colloidal iron was more effective than granular iron in achieving pH increase and metal removal and further noted that sulfate-reducing bacterial populations benefited from the pH increase and contributed to metal removal through production of sulfides.

Acid Rain Mitigation

Combustion of sulfur-containing fuels such as coal and fuel oils produces SO_2 and lesser amounts of sulfur trioxide (SO_3), which are acidic gases (DOE 1999). Hydrochloric acid (HCl) is another product of combustion. SO_2 and HCl are eye and respiratory irritants and contribute to formation of acid rain. Acid neutralization reagents play an important role in decreasing emissions of SO_2 and other acidic gases by FGD. Application of alkaline materials to affected catchment basins is a promising approach to mitigating the effects of acid precipitation.

Calcium- or sodium-based sorbents are commonly employed to control acidic gases from combustion. These materials react with SO_2 and SO_3 to form sulfite and sulfate salts and neutralize HCl to sodium chloride and water. The sorbents can be injected in either dry or wet states. In dry sorbent injection, the dry sorbent is injected directly into the furnace or flue gas duct. There, the dry particles react with the acidic gases and are subsequently removed by particulate control devices. In wet FGD, the sorbent is dissolved in or slurried with water. The flue gas contacts the solution or slurry in a scrubber. Because of their low cost, limestone and lime are the most frequently used sorbents, accounting for more than 90% of U.S. FGD system capacity (DePriest and Gaikwad 2003).

Newton et al. (1996) reported the application of limestone on two tributary catchments to a small lake in the western Adirondack region of New York. Acid neutralizing capacity of the streams was

immediately increased as the result of the dissolution of calcite that fell directly into the stream channels and adjacent wetlands. Continued acid neutralization capacity over the next year was attributed to surface runoff and interflow from soil that had received limestone. Better results in one stream than in the other apparently resulted from more extensive wetlands. Sakamoto et al. (2001) considered the ash of coal-biomass briquettes as a source of alkalinity for mitigating the effect of acid rain on soils in the Chongqing City region of China. These briquettes are made using hydrated lime as a binder, and their ash is highly alkaline. Amending soil with 5% ash raised the pH of leachate from 5 to a range of 6.5–7.6. Leachate concentrations of copper were below the environmental standard for irrigation water, but chromium concentrations exceeded the standard during part of the experimental period.

Water and Water Treatment

Water Softening

High concentrations of calcium and magnesium ions in water can be troublesome. These ions tend to combine with soaps or detergents, forming an insoluble scum that stains laundered clothes. Calcium can precipitate with carbonate ions in water, forming deposits of hard scale inside of pipes that reduce flow capacity.

Removal of calcium and magnesium ions from water is called softening. One of the popular, large-scale methods for softening water is to add quicklime (after slaking) or hydrated lime. The lime is mixed with water to form a slurry, which is added to the water in a mixed reactor. Hydroxyl ions from the lime increase the hydroxyl ion activity (i.e., raise the pH) of the water. This converts bicarbonate ions in the water to carbonate ions, which precipitate with calcium. The overall reaction is

This reaction is limited by the concentration of bicarbonate ions in the water. In some cases, sodium carbonate is added along with lime to act as an additional source of carbonate ions. Sodium carbonate is also used as a water softener in laundry detergents.

Coagulant Aid for Removal of Clay Particles

Micrometer-sized clay particles that are washed into surface waters by runoff are difficult to remove directly by separation processes such as sedimentation or granular media filtration. Hydrolyzing salts of aluminum or iron react in water to form aluminum or iron hydroxide complexes and precipitates that coagulate the clays. The resulting flocs settle much faster than the individual clay particles and can be economically removed from water by sedimentation.

Using the addition of ferric iron to water as an example, as shown previously in Equation (8), it is apparent that bicarbonate ions are consumed and CO_2 is produced by the hydrolysis of this metal in water. The same is true of trivalent aluminum. Decreasing the bicarbonate ion concentration and increasing the CO_2 concentration both tend to depress pH, particularly in surface waters having low initial alkalinity. Feeding of reagents such as lime along with the coagulant is therefore commonly required to maintain an appropriate pH range for the coagulation process.

Phosphorus Removal

Phosphorus, which occurs in the form of phosphates in natural systems, is an essential plant nutrient. Excessive phosphorus concentrations can stimulate the growth of microalgae and aquatic plants in surface waters, a process called eutrophication. In watersheds that are sensitive to phosphorus, wastewater dischargers may be required to remove phosphates from their treated effluents.

One of the methods used for removing phosphates from water is lime addition. This raises the pH of the water, converting H_2PO_4^- and HPO_4^{2-} ions to PO_4^{3-} . The phosphate ions, in turn, precipitate with calcium and hydroxyl ions, forming solid hydroxylapatite,

that can be collected as sludge. This reaction occurs simultaneously with the precipitation of calcium carbonate. Because calcium ions are typically present in much larger concentrations than phosphate ions, most of the sludge produced will consist of calcium carbonate.

Alkaline Stabilization of Municipal Wastewater Sludges (Biosolids)

Biosolids result from the treatment of municipal wastewater sludge to substantially decrease vector attraction potential and microbial pathogen content. Recycling of biosolids through land application is widely practiced in the United States and other parts of the world. One of the most popular methods for sludge treatment is lime addition. Addition of hydrated lime to sludge can create pH levels up to 12.4, which destroy harmful microbes and provide a vector attraction barrier. Use of quicklime, in addition to raising pH, also dehydrates the sludge and elevates its temperature, increasing the level of disinfection.

EPA regulations (2005) create two classes of biosolids, A and B. Class B biosolids contain pathogen levels that are low enough for application to agricultural land, providing that public access is restricted. Class B requirements can be met with lime by raising the pH of the biosolids to more than 12 for 2 hr and then maintaining the pH at 11.5 or higher for another 22 hr. Class A biosolids contain pathogen concentrations that are low enough to allow use with few restrictions. Examples include household gardens and nurseries, as well as agricultural land. To meet Class A requirements using lime, the Class B elevated pH requirements are combined with elevated temperatures (e.g., 70°C for 30 min) or other EPA-approved time/temperature processes.

Advantages of lime sludge stabilization are low capital costs and flexibility to produce either Class A or B biosolids. This treatment approach also effectively destroys odors caused by sulfur species such as sulfides and mercaptans (National Lime Association 2000). Ammonia, however, is volatilized through pH elevation, creating ammonia odors that must be controlled. The total quantity of solids for disposal is increased through alkaline stabilization (Oleszkiewicz and Mavinic 2001).

SUMMARY

The commonly used acid neutralization reagents include caustic soda, soda ash, lime, limestone, magnesia and magnesium hydroxide, and ammonia. In addition to their applications for neutralizing acidic wastewaters, including acid mine drainage, these reagents are also employed to soften water, clarify water and wastewater, remove phosphorus from effluents, condition and disinfect municipal wastewater sludges, and remove SO_2 and other acidic gases from combustion flue gases. Novel materials such as alkaline industrial wastes and zero-valent iron have been useful in passive systems for acid mine drainage control. Expanded consumption of the acid neutralization reagents will be needed to achieve environmental quality goals in the future.

Asbestos Substitutes

Robert L. Virta

INTRODUCTION

Asbestos substitutes are materials that have properties similar to those of asbestos and are used to replace asbestos in manufactured products. Substitutes were used first in quantity in the 1970s when concerns first arose about adverse health effects of asbestos. To replace asbestos, a wide variety of substitutes have been developed that can be fibrous or nonfibrous, organic or inorganic, and natural or synthetic; each has its own unique physical and chemical properties. Lists of asbestos substitutes are given in Table 1 (fibrous and nonfibrous asbestos substitutes) and Table 2 (mineral and organic asbestos substitutes). In most products, asbestos substitutes have been used for a sufficiently long period of time so that they are now considered an integral part of the product and the term *asbestos substitute* is almost outdated.

Differing from asbestos substitutes, *alternative products* replace an entire asbestos-containing product rather than just the asbestos used within the product. For example, cast-iron and polyvinyl-chloride (PVC) pipes are alternative products that are used in place of asbestos-cement pipe.

HISTORY

Serious interest in asbestos substitutes developed during World War II because of possible disruptions of asbestos supplies for strategic wartime applications. In the United States, research focused primarily on using glass fiber and mineral wool. Because supply lines were not disrupted, the use of substitutes did not become critical to national security. The Germans, having been isolated from all asbestos sources during the war, expanded their investigations to include cellulose, glass wool, iron wire, plastics, steel wool, synthetic rubber, and treated paper as potential substitutes for asbestos (Bowles 1959). Serious interest in substitutes waned after World War II because of the large demand for asbestos-based construction materials in postwar Asia and Europe and the stockpiling of strategic grades of asbestos by the U. S. government in the late 1940s (Bowles 1959; Virta 2003).

After a 20-year hiatus, interest in marketing materials as asbestos substitutes returned in the 1970s. By this time, researchers had established a positive correlation between worker exposure to asbestos fibers and respiratory cancer diseases (Selikoff, Chu, and Hammond 1964; WHO 1986; Murray 1990). Companies that mined asbestos, manufactured asbestos products, and eventually installed or used asbestos products began to face an increasing

^{*} Dependent on material; for example, wollastonite is acicular, palygorskite (attapulgite) is fibrous, and PTFE can be manufactured in nonfibrous or fiber shapes.

[†] Materials in bold type are more commonly used asbestos substitutes.

number of class-action lawsuits (Butler 2002; White 2002). Public opposition to the use of asbestos also hastened the removal of asbestos from commercial products. As a result, there was a sharp decline in asbestos use, beginning in the 1970s, that was balanced by research for and an increasing use of asbestos substitutes or alternative products (Virta 2003).

PRODUCTION AND MARKETS

U.S. Production

Data on the production and consumption of asbestos substitutes are not available. Substitute materials, such as cellulose, fiberglass,

sepiolite, and wollastonite, and alternative products, such as corrugated aluminum sheet, ductile-iron pipe, metallic brakes, and wood siding, were in use before the asbestos health issue arose. Sales statistics by industries manufacturing these materials generally did not indicate if increases in sales after the early 1970s resulted from expansion of existing markets or the opening of new markets for asbestos substitutes. The wide number of substitutes and alternative products available and the many different formulations for products further complicate the estimation process. The magnitude of overall substitute use, however, can be estimated by examining data on asbestos production and consumption (a full review of asbestos data is given in the Asbestos chapter in this book).

Apparent U.S. consumption of asbestos increased through the 20th century to a peak of about 800,000 t in 1973 (Buckingham and Virta 2002; Virta 2003). In 2003, apparent U.S. consumption was 5,000 t (Virta 2004), suggesting that asbestos substitutes and alternative products in the United States replaced sales of roughly 795,000 tpy of asbestos. If it were not for the health issue, expansion of most asbestos markets probably would have continued beyond the early 1970s, with the possible exception of asbestos for automotive brake manufacture. The downsizing of automobiles in North America and the introduction of front-wheel drive in the 1970s resulted in the increased use of semimetallic disk brake pads and non-asbestos organic brakes, both of which did not require asbestos in their formulations (Brunhofer, Aldrich, and Jacko 1980; Jacko and Rhee 1992). This occurred as asbestos usage began to fall out of favor, so it is difficult to assess the exact impact. At a minimum, the shift to brakes that used less asbestos would have slowed growth of asbestos sales in the friction products sector. In general, though, the sharp decline in U.S. sales of asbestos for asbestos-cement pipe and sheet, electrical and thermal insulations, flooring, friction products, packings, plastics, and textiles after 1973 suggests that the asbestos health issue, rather than changing technology, was the most significant contributing factor to the increased use of asbestos substitutes and alternative products.

U.S. Markets

Markets for asbestos substitutes include cement products, coatings and compounds, flooring, friction products, gaskets and packing, insulation, roofing, textiles, and a variety of small-tonnage applications. Estimates can be made for individual U.S. market losses for asbestos and corresponding gains for substitutes and alternative products by using the breakout of U.S. asbestos consumption during

the peak consumption year, 1973, as a guide. In that year, manufacturing used the following amounts of asbestos (Clifton 1975):

- Flooring products—198,000 t
- Unknown or miscellaneous applications—roughly 158,000
- Asbestos-cement pipe—151,000 t
- Roofing products—79,000 t
- Friction products—72,000 t
- Asbestos-cement sheet—58,000 t
- Packings and gaskets—24,000 t
- Insulation—23,000 t
- Asbestos paper products—16,000 t
- Textiles—16,000 t

Under the “unknown” category, an estimated 35,000 t to 40,000 t was probably sold for coatings and compounds. In 2003, the breakout of asbestos consumption was about 1,170 t for coatings and compounds, 2,800 t for roofing products, and 678 t for unknown or miscellaneous products (Virta 2003). These figures represent 30- to 200-fold declines in asbestos use for coatings, roofing, and other uses, and a complete loss of sales for other manufacturing sectors between 1973 and 2003. For all categories, asbestos substitutes or alternative products have replaced most, if not all, types of asbestos.

World Production

Although data on the worldwide use of asbestos substitutes are not available, the impact of the asbestos health issue appears to have occurred at a slightly slower pace outside the United States. World asbestos consumption (assumed to be equal to production until about 1998) peaked around 1975, 2 years after peak consumption in the United States. In 1975, world asbestos production (consumption) was estimated to be about 5.09 Mt, but by 2002, it had declined to 2.13 Mt. Based on trade balance calculations for 2000, asbestos consumption in 2002 was estimated to be less than 2.0 Mt, suggesting that the use of asbestos substitutes and alternative products had reduced annual world consumption of asbestos by at least 3 Mtpy, or 59% since 1975 (British Geological Survey 2002; Virta 2003).

World Markets

Individual markets for substitutes outside of the United States also are not well documented in most countries. Use of asbestos for construction activities (primarily asbestos-cement products but also including caulks, insulation, putties, roofing, sealants, stucco, tiles, etc.) was estimated to be 3.55 Mt in 1974 and 3.83 Mt in 1988. Use in friction products (brakes and clutches) was 310,000 t in 1974 and 152,000 t in 1988. Other uses were 560,000 t in 1974 and 338,000 t in 1988 (Roskill Information Services Ltd. 1990). Based on these estimates, the quantity of asbestos used in friction products and other applications declined 44% between 1974 and 1988 worldwide. Use of asbestos in construction applications, however, increased slightly over this same time period, with overall market share increasing from 80% to 89%. A major contributing factor to the popularity of asbestos-cement products is their cost-effectiveness (Institute for Environment and Health 2000). In 2000 asbestos-cement products were estimated to account for more than 98% of world asbestos consumption, or about 2.0 Mt (Virta 2003). Despite this increase in market share, sales of asbestos for cement products have declined more than 1.7 Mt since 1988, due to the use of asbestos substitutes and alternative products.

Substitutes and Alternative Products

The development of asbestos substitutes and products was accomplished primarily through two methods: the expansion of markets

Table 3. Examples of alternative products

Asbestos-cement pipe	Ductile-iron pipe
	PVC pipe
	Prestressed concrete
	Reinforced concrete pipe
Asbestos-cement sheet and shingles	Aluminum siding
	Cement sheet
	Corrugated aluminum sheet
	Corrugated fiberglass sheet
	Corrugated PVC sheet
	Corrugated steel sheet
	Vinyl siding
Coatings and pipeline wrap	Wood siding and shakes
	Asphalt coatings
	PE films
Floor covering	Urethane tape
	Carpeting
	Dimension stone tile
	Quarry tile
	Vinyl flooring and tile
Friction products	Wood floor
	Metal-bonded ceramic compositions or sintered brakes
	Nonasbestos organic
Packings and gaskets	Semimetallic disk brakes
	Copper, cork, expanded graphite, glass fiber, natural rubber, PBI, PTFE
Roofing	Single-ply membranes

Source: EPA 1980, 1988; Hodgson 1985, 1989; Roskill Information Services Ltd. 1990; Harrison et al. 1999.

of existing products to fill the void left by declining asbestos consumption; and direct substitution of asbestos in former asbestos-based products (Meylan et al. 1978; EPA 1980, 1988; Hodgson 1985; Roskill Information Services Ltd. 1990; Harrison et al. 1999; see Tables 1, 2, 3, and 4). Examples of substitutes include cellulose, fiberglass, PAN fibers, PE fiber, and PVA fibers. Examples of alternative products are ductile-iron pipe, PVC pipe, prestressed concrete, and reinforced concrete pipe (Hodgson 1985; Roskill Information Services Ltd. 1990; Harrison et al. 1999).

Rate of Substitution for Asbestos

Asbestos Substitutes

Although the use of alternative products was readily accepted, the direct replacement of asbestos in products was a more gradual process, because the suitability of the substitutes had to be evaluated prior to their extensive use in any given product. Cost, longevity, performance, and potential health risks were critical factors to consider (Hodgson 1985). The difficulty of replacing asbestos varied for different markets. Of the major U.S. asbestos markets, the rate of asbestos replacement has been much slower for brake markets than for most other products. In 1983, 10 years after peak U.S. asbestos consumption, sales of asbestos for friction products had declined only 33% compared with decreases of more than 75% for other major U.S. end-use markets. Engineers had to overcome problems with glazing of brake surfaces that reduced stopping performance; different heat-resistance characteristics of the substitutes; and moisture absorption that reduced stopping performance until the brakes were applied a sufficient number of times to dry

Table 4. Examples of asbestos substitutes and alternative products

Asbestos-cement pipe	Cellulose fibers, ductile iron, fiberglass, mica, PAN and PVA fiber, PVC pipe, prestressed concrete, reinforced concrete pipe, wollastonite
Asbestos-cement sheet	Aluminum siding, cellulose fibers, corrugated fiberglass panels, corrugated PVC panel, fiberglass, fibrillated PP, PAN and PVA fiber, vinyl siding, wood
Coatings and compounds	Aramid fiber, carbon fiber, cellulose fiber, clay, fiberglass, PE films, limestone, rubber membrane roofing, mica, PE fiber, PP fiber, talc, wollastonite
Flooring	Carpeting, ceramic tile, clay, fiberglass, PE pulp, silica, talc, vinyl compositions, wood
Friction	Aramid fibers, cellulose, ceramic fiber, fiberglass, metal (i.e., brass, bronze, copper, and iron) fibers, palygorskite (attapulgite), PAN fiber, potassium titanate, semimetallic brakes, sepiolite, steel fibers, vermiculite, wollastonite
Insulation	Calcium silicate board, cement board, ceramic fiber, fiberglass, mica, mineral wool, vermiculite
Packings and gaskets	Aramid fiber, carbon fiber, cellulose fiber, ceramic fiber, cork, fiberglass, graphite, mica, metal gaskets, mineral wool, PTFE, rubber sheeting
Paper and paperboard	Ceramic fiber, cellulose, fiberglass, mica, PTFE, vermiculite, wollastonite
Pipe wrap	Nonfibrous minerals, plastic coatings, urethane coatings
Plastics	Aramid fiber, carbon fiber, fiberglass, fumed silica powder, mica, PTFE, potassium titanate, wollastonite
Tape	Carbon-based tape, cellulose, urethane tape
Textile	Aramid fiber, carbon fiber, ceramic fiber, fiberglass, mineral wool, PBI fiber

Source: EPA 1980, 1988; Hodgson 1985, 1989; Roskill Information Services Ltd. 1990; Harrison et al. 1999.

out. There also was brake pad or shoe vibration, which caused “shuddering” of the brake when applied, and rapid wear of many of the early asbestos substitute brakes that manufacturers had to eliminate through design modifications (Lam and Yesnik 1998).

Alternative Products

The rate of replacement depended on the market. In the United States in 1975, cast-iron pipe comprised 75% (by mileage) of water main pipe in place; asbestos-cement pipe, 13%; steel pipe, 6%; reinforced concrete pipe, 2%; plastic pipe, 1%; and other types of pipe, 3%. With sewer mains, the distribution was 67% vitrified clay pipe; 16% reinforced concrete; 5% asbestos-cement pipe; 3% cast-iron pipe; 2% plastic pipe; and 7% other (EPA 1980). The transition to alternative pipe products and cellulose or polymer fiber-reinforced pipe involved only a small portion of the total U.S. water main and sewer pipe markets. This contrasted with the resilient flooring market, where asbestos products accounted for 91% of sales in 1975, and friction product markets, where most brakes were asbestos-based prior to the middle 1970s (Wright 1978; Jacko and Rhee 1992).

PRICES

Prices for asbestos substitutes vary considerably. Mineral substitutes are less expensive than more process-intensive synthetic fibers. Because of the additional processing, substitutes that have been surface treated will sell for a higher value than untreated substitutes. Also, substitutes having narrower specification ranges generally will be more expensive. Average prices for mineral substitutes and synthetic substitutes are listed in Tables 5 and 6, respectively. These

should be used only as a guideline, because prices are negotiated between seller and buyer according to lot size, frequency of purchase, fiber availability, production costs, and so forth.

TYPES OF ASBESTOS SUBSTITUTES

Fibrous substitutes include mineral and organic fibers such as palygorskite (attapulgitite), sepiolite, acicular wollastonite, and PP fibers. Non fibrous substitutes are minerals, mineral groups, or rocks such as diatomite, mica, perlite, serpentine, silica, and talc (Table 1). The natural substitutes encompass minerals and a limited number of organic materials such as cellulose and wool. Synthetic substitutes include fiberglass, mineral wool, synthetic gypsum fibers, synthetic wollastonite, and various polymer fibers (Meylan et al. 1978; Hodgson 1985; EPA 1988; Harrison et al. 1999; Institute for Environment and Health 2000.)

The diversity of materials required to replace asbestos reflects its versatility. To understand what is required of an asbestos substitute, it is best to examine the properties of asbestos. These are fully discussed in the Asbestos chapter in this book.

Table 7. Properties imparted to products by asbestos substitutes

Application	Important Properties
Cement pipe	High green strength, good tensile strength, resists alkali attack, high impact strength, drains well during manufacture, heat resistant
Cement sheet	High tensile strength, heat resistant, resists chemical attack, resists rot and corrosion, and nonflammable
Coatings and compounds	High viscosity, resists sagging, reduced oxidation and deterioration, low cost, thixotropic, heat resistant, resistant to chemical attack
Friction products	Heat resistant, low heat conductivity, durable, low cost
Insulation	Heat resistant, low heat conductivity, durable, low cost, does not deteriorate under exposure to water
Packing and gaskets	Flexible, heat resistant, does not deteriorate under pressure, corrosion resistant, resists chemical attack, low thermal conductivity, tear resistant, dimensionally stable, resists crushing
Paper	Resists chemical attack, dimensionally stable, heat resistant, resists rot and corrosion, nonflammable, high tensile strength, relative low price
Plastics	Heat resistant, increased stiffness, improved dielectric strength, easy processing
Roofing	High viscosity, resists sagging, reduced oxidation and deterioration, low cost, thixotropic
Textiles	Heat resistant, flexible, durable, resists chemical attack, low thermal conductivity, high electrical resistance

Asbestos Substitutes

Asbestos substitutes are chosen according to their individual properties, how the substitute affects the manufacturing process, and whether the properties imparted to the final product by the substitute make it competitive in cost and performance with other products (Hodgson 1985; Pye 1989). The ideal substitute would serve the same function in commercial products as asbestos (Table 7).

Minerals and Rocks

Minerals and rocks that have been used in place of asbestos include biotite, diatomite, graphite, muscovite, palygorskite (attapulgitite), perlite, serpentine, silica, talc, vermiculite, and wollastonite. The mineral substitutes are chosen for chemical inertness, fibrosity or platyness, flexibility, hardness, heat conductance, reinforcing properties, thermal stability, and/or thixotropic properties (Table 8). Only a small number of the substitutes possess more than a few of these characteristics. For example, diatomite, perlite, and vermiculite do not physically resemble asbestos, but they are used as substitutes because of their thermal stability (Hodgson 1985, 1989; *Industrial Minerals* 1987). In many cases, these minerals were competitors with asbestos before the asbestos health issue arose. As public opposition to the use of asbestos grew, the use of these minerals expanded as they displaced asbestos. It was only then that they became asbestos substitutes. The use of perlite and vermiculite in heat-insulating board and cement products are good examples of competing minerals that began to replace asbestos after concern arose about health issues (Hodgson 1985; Benbow 1987; Kendall 2000).

Sheet Silicates. Muscovite, serpentine, and vermiculite are sheet silicates and have a platy morphology (Deere, Howie, and

Zussman 1966). The platy shape of these minerals provides a large contact area between the particle and the matrix, improving the flexural, impact, and tensile strengths of the product (Trivedi and Hagemeyer 1994). In general, platy minerals do not provide the same degree of reinforcement as asbestos in the product because they are not fibrous. The sheet silicates used as asbestos substitutes are thermally stable at moderate temperatures. At low to moderate temperatures, they lose adsorbed and structural water but do not begin to decompose until temperatures exceed approximately 800°C, with melting points well above 1,000°C (Hodgson 1985). Operating temperatures for products containing these and other minerals are below the melting temperatures of the individual minerals. For example, the working temperature of a nonasbestos high-temperature insulating board product containing talc is about 815°C, below the temperature of 950°C at which talc alters to enstatite and quartz (Cavicchio 1981).

Vermiculite has an advantage over other sheet silicates in that it exfoliates (the individual sheets separate) when heated rapidly to 900°C. The exfoliated product is stable at moderate to high temperatures. Exfoliated vermiculite is an excellent thermal insulator because of the large amount of void spaces in the expanded platelets (Hodgson 1985). Fire ratings above 900°C are reported for some vermiculite products. One company found that working temperatures of glass fiber products that have been coated with chemically delaminated vermiculite increased from 550°C to more than 900°C (Benbow 1987).

As a competitor and also a substitute for asbestos, vermiculite is used as loose-fill insulation and spray-on insulation. It also is used to produce insulation board, fire-resistant plasterboard, and as an additive in cements (Meisinger 1985; Benbow 1987; Hindman 1994).

Mica is used to a much lesser extent as a substitute for asbestos. Its platy morphology and thermal stability enable it to be used primarily in insulating board. Because it is not as effective a reinforcer as asbestos, it is usually supplemented with fibrous additives such as cellulose and fiberglass in substitute applications (Hodgson 1985; Benbow 1987). Mica may be used in brakes as a nonfibrous reinforcer (Jacko and Rhee 1992).

Talc has been used in gaskets, insulating board, and vinyl tile, but its primary use is as a component among many inorganic types

of filler and not as a direct substitute for asbestos (Cavicchio 1981; Hanson and Smith 1981; Lindeman and Andrew 1982).

Lizardite, a form of serpentine, is a sheet silicate with the same composition and many of the same physical properties as chrysotile. It is abrasive, resists chemical attack, and is thermally stable. Lizardite is promoted as a replacement for asbestos in brake pads, insulating board, and a variety of other products (Hedman Resources Ltd. 2004). As with the other sheet silicates, lizardite would not be a direct replacement for asbestos because it is not fibrous.

All of the platy minerals are as resistant to chemical attack as asbestos (Wypych 1999). These minerals are competitively priced with most grades of chrysotile (Table 5) and are widely available (see the individual mineral chapters in this book for details on production and availability of these and other mineral substitutes).

Clays. Palygorskite (attapulgitite) and sepiolite are clay minerals. They are also sheet silicates, but rather than being platy, they have a lath-like structure that is fibrous in appearance (Grim 1968; Hodgson 1985). They are moderately good reinforcers because their fibrous morphology gives them a large surface area, although the fibers are not as long as those of asbestos. Palygorskite and sepiolite lose water from their structures when heated to moderate temperatures (350°C to 600°C) and convert to clinoenstatite above 800°C (Hodgson 1985). They have long been used in products such as caulk, grease, joint compounds, paints, and stucco (Russell 1991). Before asbestos fell out of favor, both competed with asbestos as thixotropic agents and reinforcers. Palygorskite (attapulgitite) has been used as a direct substitute for asbestos in asphalt compounds (Clarke 1985; Russell 1991), while sepiolite is used as a direct replacement for asbestos in some joint compounds (Russell 1991). Research on their use as a replacement in brakes, cement pipe products, and vinyl tile also has been undertaken in the past (Hodgson 1985). Palygorskite and sepiolite are competitively priced with most grades of chrysotile (Table 5) and are widely available.

Graphite. Graphite is a platy mineral composed of carbon (Deere, Howie, and Zussman 1966) and is an excellent nonabrasive lubricant. It is stable at high temperatures, makes excellent packing in its expanded form, and is resistant to chemical attack (EPA 1980; Taylor 1994). Generally mentioned only as a substitute for asbestos

in valve packing applications (Meylan et al. 1978; Parkinson 1986a, 1986b; EPA 1988), graphite is priced competitively with chrysotile (Table 5). Adequate supplies of graphite are available to meet demand for asbestos substitute applications.

Wollastonite. Wollastonite is a single-chain silicate called a pyroxenoid. Stable at temperatures up to 1,540°C (Deere, Howie, and Zussman 1966; Hodgson 1985), it often occurs in a fibrous habit; however, its fibers are not flexible like chrysotile fibers. Wollastonite is fairly resistant to chemical attack but is soluble in strong acids (Hodgson 1985; Bauer, Copeland, and Santini 1994). As with mica and vermiculite, products manufactured with wollastonite are stable at temperatures lower than its melting point. For example, insulation boards containing wollastonite can be used up to temperatures of about 760°C, although wollastonite is stable up to about 1,500°C (Bolger 1998). Priced competitively with asbestos (Table 5), it is already used commercially, so availability is not an issue (Patton 1973; Ciullo 1996; Wypych 1999).

During the 1970s and 1980s, consumption of wollastonite was reported to have doubled for asbestos substitute applications. By 1994, consumption of high-aspect-ratio wollastonite was estimated to be between 35,000 t and 40,000 t for substitute uses. It primarily replaces asbestos in aluminum and asphalt roof coatings, cement board, friction products (brakes), and insulation boards. Wollastonite is used to improve the flexural strength of cement; improve the friction coefficient, green strength, and heat dissipation in brakes; and improve flexural and tensile strengths and heat resistance in insulation board (Fattah 1994). It also improves the tensile strength and the thermal stability of polymers and improves the mechanical strength of paint films (Bolger 1998).

Gypsum. A naturally hydrated calcium sulfate, gypsum also can be synthesized easily in a partially hydrated or anhydrous form. In its partially hydrated form, it is called hemihydrate calcium sulfate, while the anhydrous form is called anhydrite (Jorgensen 1994). In the past, a gypsum fiber product consisting of long, strong, and thin fibers that exhibited good reinforcing properties was used. The fibers were nonabrasive, stable up to a temperature of 1,000°C, and stable in mild acids and bases (Virta 1994). These fibers no longer appear to be available on the market, and their manufacture is believed to have ceased.

Diatomite and Perlite. Two other materials discussed as asbestos substitutes are rocks rather than minerals: diatomite and perlite. Diatomite is a rock composed of amorphous silica shells of diatoms, which are microscopic plants. These skeletal remains range from equidimensional to disk shaped to rod-like, depending on the species. Diatomite has a large surface area, low density, and is stable up to temperatures greater than 1,400 °C (Hodgson 1985; Breese 1994). Because diatomite was used as a filler and extender and in thermal insulations before the asbestos health issue arose, it was first a competitor with asbestos rather than a substitute. Major uses as a substitute are in insulation applications, often in combination with a fibrous reinforcing material such as asbestos (now obsolete), fiberglass, and mineral wool (Hodgson 1985). It has been used as inert filler in non asbestos brakes and millboard (Cavicchio 1981; Lam and Yesnik 1998). Diatomite is priced competitively with chrysotile (Table 5) and is widely available.

Perlite is an amorphous or glassy volcanic rock with a high silica content. When heated, it expands into glassy foam. Perlite has a low density, is chemically inert, and is an excellent thermal insulator (Hodgson 1985; Breese and Barker 1994). Like diatomite, perlite already was used as an insulator (loose fill, pipe insulation, and roof insulation board) and in acoustical tile, concrete, and plaster before health concerns about asbestos became an issue (Hodgson 1985; Breese and Barker 1994). It also has been used as a

substitute for asbestos for filtering liquids (Pye 1989). Because perlite is not fibrous, it often is used in conjunction with fibrous materials in insulation panels (Hodgson 1985). Perlite is competitively priced with chrysotile (Table 5) and widely available.

Organic Substitutes

Organic substitutes are either natural or synthetic. The natural fiber substitutes are animal, vegetable, and wood. Animal fiber normally refers to wool. Vegetable fiber is derived from the bark and leaves of plants such as flax, hemp, jute, and ramie. Wood fiber is obtained by chemically and/or thermally processing wood pulp (Hodgson 1985; Barkalow and Whistler 2000).

Cellulose. Because cellulose is fibrous, it is used to improve tensile strength of many products. An organic material, cellulose has a low density, almost half that of asbestos (Wypych 1999). Cellulose fibers are resistant to alkaline attack and disperse well in suspensions, but they have a lower tensile strength than asbestos, are flammable, and absorb more water than asbestos during manufacturing (Hodgson 1985, 1989).

As early as the 1950s, cellulose was used in combination with asbestos in partition boards and cement products (Hodgson 1985). Cellulose-based roofing felts have long competed with asbestos roofing felts (EPA 1988). As an asbestos substitute, cellulose use has expanded to include adhesives, asphalt compounds, caulking, cement board products, friction products, gaskets, and millboard (Cavicchio 1981; EPA 1988; Annemaier and Graf 1996; Hagens 2003; Merkley and Luo 2004). Cellulose fiber is readily available worldwide, and prices are competitive with those of asbestos (Table 6).

Other Cellulose Fibers. Bamboo fiber, hemp, jute, and sisal are vegetable fibers that have been considered for use in place of asbestos. Their properties are not significantly different from those of cellulose. Because of the wide availability of cellulose derived from wood fiber, however, the use of bamboo, hemp, jute, and sisal fibers as asbestos substitutes is limited (Hodgson 1985, 1989).

Wool. Wool, which is fibrous and can be woven, is the only animal fiber used as an asbestos substitute. It is a good thermal insulator and can withstand short-term exposures to high temperatures without burning. Wool's heat resistance can be enhanced with an aluminized coating. It is widely available but has been used in only a few substitute applications such as heat-resistant textiles (Hodgson 1985, 1989).

Polymer Fiber. Many different types of synthetic or organic materials are used as asbestos substitutes. Organic-based substitutes include fibers composed of polyamide (PA; including aramid and nylon), PAN, PBI, PE, polyester (PT), PP, PVA, and PTFE fiber and sheet (EPA 1980, 1988; Hodgson 1985, 1989; *Materials Engineering* 1987; Harrison et al. 1999; Institute for Environment and Health 2000). These are all polymers or plastics consisting of long-chain organic molecules. Another organic-based substitute is a fiber composed of graphitized carbon (Hodgson 1989; Wypych 1999; Block 2002).

Most polymers are recognized by their commercial names. Kevlar or Nomex are trade names for aramid fibers, which are used to make products such as fire-resistant textiles and bulletproof vests (Hodgson 1985; *Materials Engineering* 1987; Wypych 1999). Nylon is a synthetic fiber used in clothing, while PP is a polymer used to produce building and household materials such as drainpipe, plastic outdoor furniture, and siding. PVA fibers are used in textiles and carpet fibers, and Teflon is an example of a PTFE fiber (Wypych 1999; Block 2002; Carraher 2004).

Most polymer-based substitutes are used to improve flexural and tensile strengths of products when incorporated as fibers. The

* Fibers may char without losing significant physical characteristics.

† na = not available.

tensile strength of polymer fiber is dependent on the composition and structure of the organic material. Aramid fibers are among the strongest of the organic fibers, approaching the tensile strength of asbestos, and are thermally stable (Hodgson 1985, 1989; EPA 1988). The use of PA, PAN, PE, PT, PP, PVA, and PTFE is limited to situations where temperatures generally do not exceed 200°C. PBI and some forms of PA are thermally stable to about 300°C, although all polymers will begin to soften or char at higher temperatures (Hodgson 1989). All of the organic-based substitutes have low densities. For a given fiber loading, a smaller mass of organic fiber is required than with asbestos (Table 9). Polymers such as PE, PP, and PTFE are resistant to attack by many acids and bases (Hodgson 1989; Institute for Environment and Health 2000). Polymer fibers, which cost more than asbestos, are generally available in sufficient quantities to permit wide-scale use (Hodgson 1985; see Table 6).

Carbon Fiber. Although carbon fiber has a composition identical to graphite, it is a synthesized fibrous material. Certain varieties have an extremely high tensile strength and are excellent additives to improve mechanical strength. Additionally, carbon fiber can be woven and molded into intricate shapes. All varieties are good electrical conductors and can be used at temperatures approaching 3,000°C in inert atmospheres (Hodgson 1985, 1989; Wypych 1999; AZoM.com 2004; see Table 9). Although carbon fibers are readily available, they are more expensive than asbestos (Hodgson 1989; see Table 6).

Nonfibrous Polymer Substitutes. Manufacturers also have investigated the use of nonfibrous organic-based substitutes in some applications. Because they have the same compositions as the fibrous organic materials, they have the same properties. The nonfibrous organics generally are developed for specific end-use markets. Modified PP sheet for use in asbestos-cement sheet and shaped PTFE parts for gaskets are two examples of nonfibrous organic-based substitutes. The nonfibrous materials are widely available (EPA 1980, 1988; Hodgson 1989; *Materials Engineering* 1987; Harrison et al. 1999).

Synthetic Inorganic Substitutes. Fiberglass, mineral wool, and ceramic (refractory) fibers have been used as a replacement for and competitor with asbestos for many years (Meylan et al. 1978;

EPA 1988; Hodgson 1989; Harrison et al. 1999; Institute for Environment and Health 2000). All of these forms are fibrous, with diameters generally ranging from 1 µm to approximately 25 µm. Most forms of fiberglass and mineral wool have relatively low tensile strengths although strengths are greater for specialty fiberglass products (Hodgson 1989; Wypych 1999). A large number of the fiberglass varieties can be woven. Ceramic fibers have higher tensile strengths, with some exceeding those of asbestos. Fiberglass, mineral wool, and ceramic fibers are more brittle than asbestos fibers (Hodgson 1985, 1989).

The resistance of fiberglass and mineral wool to attack by alkaline solutions varies with composition. Those with high silica content are more susceptible. For fiberglass and mineral wool, working temperatures range from 300°C to 500°C, while ceramic fibers can be used at temperatures of 1,000°C to 1,800°C (Hodgson 1989; Harrison et al. 1999; Wypych 1999; AZoM.com 2004). Fiberglass and mineral wool are more expensive than asbestos, particularly for specialty fiberglass products (Tables 5 and 6). Because commercial production of these materials is extensive, availability is not a factor.

Although most fiberglass for substitute applications consists of long fibers, shorter fiberglass lengths also have been used. Essentially the waste stream products from fiberglass manufacture, the short fibers possess almost the same properties as E glass fibers when fiberized but are less expensive. (E glass is a borosilicate glass with high electrical resistivity.) The use of these short fibers has focused primarily on plastics applications. The shorter lengths allow the fibers to be more easily mixed with the polymer and allow for higher loadings than with other fiberglass products. This reduces costs by displacing more expensive components, and the short fiberglass has been shown to improve creep resistance, flexural modulus, and thermal stability (Lancaster Fibre Technology Group 2004).

Potassium titanate whiskers are another synthetic inorganic fiber used in substitute applications. Hard and abrasive, the whiskers have diameters of 0.2 to 1 µm and lengths of 10 to 20 µm. Potassium titanate is used primarily in brake manufacture where it improves the coefficient of friction, heat resistance, tensile strength, and wear resistance of disk pads and brake linings. Because of the

health controversy of fibers, the use of balled, platy, or powder forms appears to be preferred. These offer the same friction characteristics and heat- and wear-resistance properties as the whisker form. The nonfibrous forms generally are mixed with a fibrous organic material such as aramid or with metal fibers. Generally the nonfibrous form of potassium titanate is treated with a silane or phenolic resin to improve adhesion to the matrix (Kesavan and Burmester 1999; Hikichi, Haruta, and Horiguchi 2003). Potassium titanate whiskers are also used in heat insulation products and plastics.

Table 10 summarizes some of the important properties of the fibrous asbestos substitutes.

Alternative Products. Many manufacturers, instead of searching for an asbestos substitute, choose to replace the asbestos-containing product with one that never had asbestos (Table 3). For example, ductile-iron pipe and reinforced concrete pipe have been used in place of asbestos-cement pipe. Aluminum, vinyl, or wood sidings and cement board have been competitors with asbestos-cement shingles for many years (Meylan et al. 1978; EPA 1988; Pye 1989). Ceramic, nonasbestos organic, and semimetallic disk brakes are other common alternative products (Jacko and Rhee 1992). Alternative products are practical for many applications, because they usually are existing products and do not require the manufacturer to develop a new asbestos-free product. The major concerns of customers and manufacturers when selecting an alternative product are cost and performance (Hodgson 1985; Pye 1989).

To summarize, the ideal asbestos substitute would be composed of fibers that are flexible, have a high tensile strength, have a large surface area, and can be woven. The substitute also would be a good electrical insulator; resistant to degradation when exposed to high heat or chemicals; widely available; competitively priced with asbestos; and not a carcinogen. Products manufactured using substitutes and alternative products need a proven reliability record, must be easy to use or install, and pose little health risk in manufacture and use. While none of the substitute materials possess all of these qualities, through proper engineering, substitutes have been able to replace asbestos in a majority of commercial applications, particularly in Europe and North America.

PRODUCTION METHODS

Production of mineral substitutes for asbestos is straightforward. In most cases, open-pit mining is used. The ore is crushed and milled, typically with simultaneous drying and air classification, to produce multiple products based on particle size, shape, and other physical or chemical properties. Calcination, density and magnetic separation, exfoliation, flotation, thermal expansion, and surface treatment with silanes or titanates may be required for some minerals (details of mining and processing of minerals are given in the individual mineral chapters in this book).

Fiberglass, mineral wool, and refractory (ceramic) fiber are produced from a molten state. They are manufactured from molten glass that is dripped onto a rotating disk and spun off into long strands, dripped into a stream of air or steam and stretched into long glass strands, or forced through multiple nozzles forming continuous fibers. Glass for fiberglass is manufactured using various mixtures of quartz, feldspar, soda ash, kaolin, and specially selected oxides to produce fiberglass with specific compositions. Rock, usually basalt or diabase, and furnace slag may be melted to manufacture mineral, rock, and slag wools. Refractory fibers are made from glass melts rich in alumina, boron, silicon, and zirconia (Mohr and Rowe 1978; EPA 1985; Hodgson 1985; Skinner, Ross, and Frondel 1988; Institute for Environment and Health 2000; McMahon and Wenzel 2001). Potassium titanate whisker and powder may be synthesized by reacting hydrated titanium dioxide and potassium hydroxide at 160°C to 170°C (Kesavan and Burmester 1999).

The manufacture of polymeric fibers is much more complex because the organic starting compounds are derived from petroleum. The entire process involves reacting two or more organic compounds under heat and pressure to obtain the appropriate compounds, which are then polymerized. These polymers may be dissolved and extruded through dies into a chemical bath where the extruded compounds solidify into fibers. Alternatively, the melted polymer may be passed into an air stream to form fibers. The polymer fibers may be stretched to further orient the polymer chains in the fiber and improve strength. Fiber texture also may be modified to improve the characteristics of the fiber for a particular application (Block 2002; Carraher 2004). To produce carbon fibers, PAN, pitch, or nylon thread are carbonized and then graphitized at high temperatures (Skinner, Ross, and Frondel 1988; Hodgson 1989). Cellulose fibers are obtained through the chemical processing of wood fiber (Hodgson 1985). Details of the process to obtain organic fibers are beyond the scope of this chapter but are available in references on chemical manufacturing. In general, the energy and technology required to manufacture organic fibers account for their higher prices compared with minerals and inorganic fibers.

TECHNOLOGY

Much of the difficulty with asbestos substitutes was not the development of entirely new substitute materials for asbestos, because

many materials possessed some of the same chemical and physical characteristics as asbestos. The task was to determine how to manufacture equivalent asbestos replacement products while compensating for the deficiencies of the substitute materials compared to asbestos. This has been accomplished in most cases through the use of a mixture of asbestos substitutes and alternative products (Meylan et al. 1978; Dupré 1984; Hodgson 1985, 1989; EPA 1988; Pye 1989; Virta 1994; Institute for Environment and Health 2000; and patents accessible through the U.S. Patent Office Web site [2005]).

Cement Products

Cellulose fiber has become a common substitute for asbestos in concrete pipe, although fiberglass, PAN, and PVA fibers also are used (Hodgson 1985, 1989; EPA 1988; Pye 1989; Institute for Environment and Health 2000). Because some substitutes lacked certain properties of asbestos, it was necessary to make compensations. For example, because most fiberglass is not resistant to alkali attack, an alkali-resistant fiberglass must be used in cement products. To ensure adequate reinforcing properties in cement products, high-quality cellulose must be used, and a modified curing process for pipe products had to be developed to avoid degrading the cellulose fiber. Compensation also had to be made because cellulose absorbs more water than asbestos during the manufacturing process. Poor adhesion of fiberglass and PP fibers to matrices was another problem in some of the earlier fiber-reinforced-concrete products. This necessitated modification of the cement formulation or surface treatment of the fibers to solve the problem (Hodgson 1985; Pye 1989; Institute for Environment and Health 2000).

A common substitute product for asbestos-cement pipe is PVC pipe for small-diameter pipe, and ductile-iron and concrete pipe for large-diameter pipe. Vitrified clay pipe also may be used (EPA 1988; Pye 1989). Calcium silicate, cellulose, ceramic fiber, fiberglass, mineral wool, and PP are used in sheet products (Institute for Environment and Health 2000). Fibers of alumina, aramid, carbon, cotton, hemp, jute, kraft, PVA, ramie, and sisal also have been investigated for use in sheet products (Johnson and Melling 1983). Because PP is hydrophobic, it must be surface treated and mixed with other fillers to enhance its adhesion to and dispersion with the cement matrix (Pye 1989).

Substitutes used in asbestos cement often do not offer sufficient heat resistance, so fillers such as mica, vermiculite, and wollastonite may be added (Institute for Environment and Health 2000). Concrete mixes containing nylon, PE, and PP fibers, which typically are used for driveways, floors, sidewalks, and walls, have been available for many years to control plastic shrinkage, crack growth, and permeability. Polymer mesh products also are used as a supplement to reinforcing rods in some cement products (Concrete Fibers, Inc. 2004; NPC Inc. 2004).

Coatings and Compounds

Coatings and compounds require substitutes that are nonreactive, are thermally stable at elevated temperatures, add resistance to cracking, improve fire-resistance, control viscosity, can be dispersed easily in the matrix, bind with the matrix, and/or improve weathering properties (Meylan et al. 1978; EPA 1988; Hagens 2003).

Several substitutes used in place of asbestos in paints and sealants are aramid fiber, bentonite, calcium carbonate, cellulose, ceramic fiber, fiberglass, kaolin, mica, palygorskite (attapulgite), PE fiber, PAN fiber, PP fiber, silica gel, talc, and wollastonite. Mixtures of these substitutes often are used to obtain the desirable properties (EPA 1988; Pye 1989; Wypych 1999). As with cement, adjustments must be made with coatings and compounds. For example, cellulose is not thermally stable under acid conditions, so

asphalt compound chemistry must be adjusted to be more alkaline. Also, compensation must be made for different oil absorption properties of fiber fillers in asphalt compounds, compared to asbestos (Hodgson 1985; Hagens 2003).

Flooring

In flooring, the asbestos substitute should provide a durable, smooth, and resilient surface, and make the flooring dimensionally stable (Rosato 1959; Meylan et al. 1978; EPA 1980, 1988).

For flooring felts, substitutes such as cellulose, fiberglass, PE fiber, and PP fiber, often in combination, have been used in place of asbestos. Alternative flooring products with modified vinyl composition and foam backings also have been used to compensate for the removal of asbestos (EPA 1988). Flooring primarily to replace vinyl asbestos tile has been made from modified vinyl compositions and may contain mineral fillers such as calcium carbonate, clay, fiberglass, mica, PE pulp, talc, vermiculite, and wollastonite (EPA 1988). Alternative products for flooring include carpeting, ceramic tile, and wood flooring (EPA 1980).

Friction Materials

Substitutes for friction materials should be heat resistant and have low thermal conductivity, a low noise coefficient, and high strength. They also should be moisture resistant, nonabrasive, long wearing, and bond tightly to, and disperse well in the matrix (Hodgson 1985; EPA 1988; Pye 1989; Jacko and Rhee 1992; Kobayashi 2002).

Aramid fiber, carbon fiber, cellulose, ceramic fiber, fiberglass, metal fibers (brasses, bronze, copper, and iron), mineral wool, palygorskite (attapulgite), potassium titanate, tremolitic talc, vermiculite, and wollastonite are used in various combinations to replace asbestos in brakes (Meylan et al. 1978; EPA 1980; Hodgson 1985; Jacko and Rhee 1992). Aramid fiber appears to be the predominant fiber substitute in brake and clutch applications (Pye 1989; Institute for Environment and Health 2000).

Substitution for asbestos is difficult in semimetallic drum brakes, primarily because of the curvature of the lining. Brake shoes using substitutes absorb moisture and perform poorly until the shoes are dried through use. These problems resulted in some manufacturers stopping production of semimetallic drum brake linings (EPA 1988). The use of semimetallic disk brake pads, however, has not experienced manufacturing and performance problems; in 1986, they accounted for about 85% of original equipment disk brake pads on light-to-medium-weight vehicles (EPA 1988; Jacko and Rhee 1992; Kobayashi 2002). The market share for semimetallic disk-brake sales has declined, and nonasbestos organic brakes are now the most common type of friction materials used in brakes and clutches (Kesavan and Burmester 1999).

Gaskets and Packings

Substitutes for gaskets must be resistant to heat, tears, and chemical attacks, and be nonabrasive and resilient. Packings, which are used to form a seal between two moving parts, must be heat and chemical resistant, have low thermal conductivity, and seal liquids. Packings can be made with loose fiber, woven into braided products, and be made using yarns (EPA 1988).

Depending on the particular application, aramid fiber, cellulose, ceramic fiber, clay, copper, cork, diatomaceous earth, fiberglass, mica, mineral wool, PTFE, rubber, talc, vegetable fiber, and wollastonite have been used as asbestos substitutes in gaskets and packings. Also, carbon fiber, cellulose, ceramic fiber, expanded graphite, fiberglass, PBI fiber, and PTFE are used in packings (Corbett 1986; EPA 1988; Pye 1989; Shelley 1993; Harrison et al. 1999; Institute for Environment and Health 2000).

Insulation Materials

Insulation materials, including felts, millboard (a heavy cardboard product), paper, and wools require that substitutes be resistant to heat, corrosion, and chemical attack. Additionally, they should have a high strength, low thermal conductivity, and be moisture resistant for millboard and paper applications. Specific uses include electrical insulations in appliances and electrical panels; equipment protection when handling molten glass or metal; fireproofing for safes; durable, chemical-resistant gaskets; heat insulation for automotive mufflers, furnaces, kilns, steam lines, and stoves; paneling for garages; and even partitions for offices (Rosato 1959; EPA 1988).

The most common substitute is fiberglass for moderate-temperature, low-cost insulation. Higher-temperature applications require the use of ceramic fiber (Meylan et al. 1978; EPA 1988). A variety of other substitutes, including calcium silicate, cellulose, clays, diatomaceous earth, mica, perlite, silica, talc, vermiculite, and wollastonite, can be used in millboard and papers (Cavicchio 1981; Hodgson 1985; Benbow 1987; EPA 1988; Pye 1989).

Plastics

Filler materials improve the impact and tensile strength, stiffness, resistance to deformation when exposed to heat, and electrical resistance in plastics (Hodgson 1985; EPA 1988).

Aramid fiber, carbon fiber, cotton, fiberglass, PTFE, potassium titanate, and fumed silica powder are used in place of asbestos in plastics (Meylan et al. 1978; EPA 1988; Pye 1989). Calcium carbonate, clays, mica, talc, and wollastonite also are used as inert fillers in plastics to improve strength and stiffness (Virta and Barsotti 2000).

Roofing

Roofing materials must be flexible yet dimensionally stable and resistant to rot, fire, and heat (Meylan et al. 1978; EPA 1988). In roofing felts, cellulose and fiberglass are used as substitutes for asbestos. Fiberglass- or cellulose-reinforced shingles, metal roofing, roof tile, single-ply membrane, slate, and wood shakes are alternatives to asbestos-reinforced shingles (Hodgson 1985; EPA 1988; Pye 1989).

HEALTH ISSUES

A full review of the health issue is beyond the scope of this chapter, and readers who seek more details are referred to the abundant references available in the public domain. As with almost any material, most substitutes pose some risk to humans from exposure to dust (Douglas 2001). For most of the substitute materials, exposure limits to dust have been set to reduce the risk of pulmonary disease (NIOSH 2004).

Organic fiber substitutes generally are not thought to pose a serious health risk because the fibers are not easily respired (Elmes 1989; Harrison et al. 1999; Institute for Environment and Health 2000; Douglas 2001). Also, no serious health issues have arisen with cellulose despite the fact that it is durable and does not dissolve in the lung (Institute for Environment and Health 2000).

Laboratory animals developed intraperitoneal or intrapleural cancers when glass wool, long-fiber palygorskite (attapulgitite), titanate fibers, refractory ceramic fiber, rock wool, silicon carbide, special-purpose glass fiber, and potassium titanate fibers were implanted in them; however, intratracheal cancers were not observed. In animal inhalation studies, either cancer or mesothelioma was observed using long-fiber palygorskite (attapulgitite), refractory ceramic fibers, silicon carbide fibers, and special-purpose

glass fibers. The results were inconclusive with potassium titanate fibers (Osinubi, Gochfeld, and Kipen 2000; Douglas 2001).

Carcinogenicity to humans is probably the most important consideration in the use of any asbestos substitute, given the carcinogenic nature of asbestos. Through the review of animal testing or epidemiological studies, the International Agency for Research on Cancer (IARC) has determined that some of the substitutes are carcinogenic (IARC 1997, 2002). Some implanted and injected materials were carcinogenic in animal studies, but there were conflicting results in inhalation studies using animals and in epidemiological studies (IARC 1997, 2002; Osinubi, Gochfeld, and Kipen 2000).

Materials such as diatomite (not containing quartz), graphite, mica minerals, perlite (not containing quartz), potassium titanate, pumice (not containing quartz), serpentine (not containing asbestos), talc (not containing asbestos), and vermiculite (not containing asbestos) have not been reviewed by IARC. Recommended exposure levels, however, have been established for these lung irritants (NIOSH 2004).

Of the materials reviewed by IARC, respirable cristobalite (typically found in many calcined products) and quartz are classified as Group 1 (human carcinogens; WHO 1987; IARC 1997). Although diatomite is composed of amorphous silica, deposits usually contain crystalline silica. Also, calcined diatomite may contain cristobalite.

Specialty E glass fibers, "475" glass fibers, and refractory ceramic fibers are classified as Group 2B (possible human carcinogens; IARC 2002). Palygorskite (attapulgitite) with lengths greater than 5 μm also is listed by IARC as Group 2B (IARC 1997).

Glass wool for insulation, continuous glass filament, rock (stone) wool, and slag wool are classified as Group 3 (not classifiable as to their carcinogenicity to humans) by IARC (IARC 2002). Also classified as Group 3 are wollastonite (recognized as a lung irritant), short-fiber palygorskite (attapulgitite), and diatomite (IARC 1997; NIOSH 2004).

Vermiculite typically poses little carcinogenic risk, but vermiculite mined in the past from a deposit near Libby, Montana, contained asbestos. As a result, the vermiculite industry has been under intense scrutiny (EPA 2004). In 2000, the National Institute for Environmental Health Sciences (NIEHS) investigated talc as a possible carcinogen. The agency concluded that data were inadequate to make a ruling and, as of June 2005, was still reviewing this issue (NIEHS 2001).

Questions have been raised about the health and safety risks posed in the manufacture of some of the alternative products, particularly with regard to volatile organic compounds released during the manufacture of plastic products and during metal casting.

Another health concern with substitutes is that their use has occurred mainly during the past 20 years. Given the 20- to 30-year latency period for asbestos-related diseases (Gross and Braun 1984), many still believe that an inadequate period of time has elapsed to establish the effects of long-term exposure to asbestos substitutes on human health. These issues, however, have not discouraged the use of substitutes or alternative products.

FUTURE TRENDS

In the United States, Western Europe, parts of Eastern Europe, and a few other locations, asbestos consumption has declined enough to see that the efforts to substitute for asbestos are almost complete. In these locations, substitutes probably will experience little growth that can be attributed directly to the replacement of asbestos. In fact, many asbestos substitutes have been in use for a sufficient

period of time that they should no longer be labeled as substitutes, but can now be considered an essential component of the product.

There is still sufficient asbestos use elsewhere, however, to permit a considerable expansion in sales of substitutes or alternative materials. Most of this growth will be in asbestos-cement products, which account for more than 98% of world asbestos usage. Based on growing worldwide opposition to the use of asbestos and the increasing rate at which countries are now considering bans on the use of asbestos, the displacement of asbestos by substitutes and alternative products will continue. Some specialty applications will probably remain (where it is not feasible to replace asbestos) but in most cases substitutions will be made.

ACKNOWLEDGMENTS

Many thanks go to Sara Robinson, R. T. Vanderbilt Co. Inc., and Michael J. Potter, U.S. Geological Survey (USGS), for their technical reviews of this paper. Thanks also are expressed to Robyn Sandler, USGS, for her assistance with editing and manuscript preparation.

Clay Liners and Barriers

Robert Trauger

INTRODUCTION—CLAY AS A BARRIER

Containment is a fundamentally important concept in environmental and civil engineering. Effective containment preserves quality of life and protects valuable environmental resources. Engineered clay barriers have been used for several decades as technically suitable, cost-effective solutions for containing water, wastewater, landfill leachate, and gas. Before the introduction of synthetic liner materials in the early 1980s, clay liners were the only available option for most containment applications. Thanks to the more recent development of cost-effective thermoplastic barriers (geomembranes), the quality of containment systems can be appreciably enhanced. Clay liners still play a major role in water and waste containment, however, and are often used with geomembranes.

This chapter examines the many types of clay barriers that can be used in environmental containment applications. It covers the engineering properties of these materials and the regulatory criteria used to establish the performance of clay barriers. Information on the design of these clay barriers highlights the most important concepts required to meet modern containment performance criteria. Given the breadth and complexity of this subject matter, only an overview is possible; added details can be found in the referenced documents listed at the end of the chapter.

Types of Clays Used as Barriers

Clay or clayey soils are used as barriers primarily because their particle size is small enough to limit the flow of fluids. For this reason, engineered clay barriers are rarely categorized by clay mineral species. As discussed in the section on Engineering Properties in this chapter, hydraulic conductivity is the most important property of any soil evaluated for its barrier properties. In fact, soil barriers are often described as “clay liners” even if they are not strictly clays as defined by any common classification systems, because the hydraulic conductivity of a sandy or silty soil with some clay content is often acceptable as a barrier.

The result of this performance-oriented identification is that many kinds of clay minerals have been successfully used in engineered clay barriers. Illite, kaolinite, and smectite rank among the most common species in terms of barrier clays (Goldman 1988), but often this is due as much to their ready availability as to their desirable properties. The existing literature is incomplete with respect to identifying specific mineral species in a soil used as a

barrier. Engineers have historically specified only the required performance properties of the soil and the completed liner, leaving it to the contractor to demonstrate that these properties will be achieved. Consequently, the relationship between mineral species and engineered barrier properties is not well understood.

Smectite clays, specifically montmorillonite-bearing bentonite, are also commonly used in barrier applications. Bentonite is used as an admixture to existing soils to fill fluid-conducting void spaces. Because of its water absorption and volumetric swelling properties, a small percentage of bentonite (usually less than 10% by weight) can significantly decrease the hydraulic conductivity of a porous soil. Bentonite is also used in geosynthetic clay liners (GCLs), another type of barrier that has largely replaced the practice of using bentonite as an admixture. Bentonite and attapulgite are also used in vertical cutoff barriers, applications that are less common than conventional containment barriers but are still important technologies in contaminated site remediation.

Types of Barriers

This chapter categorizes clay barriers as “horizontal” or “vertical.” Horizontal barriers are constructed by placing and compacting clay soils, or by unrolling clay-based geosynthetic products. Vertical barriers are constructed by trenching into existing soils and then backfilling the trench with clay-bearing soil or cement mixtures.

Compacted Clay Liners

Compacted clay liners (CCLs) are the most prevalent type of clay liner. A CCL is a discrete layer of soil placed on a subgrade to serve as a barrier to fluid flow. The CCL can be placed on subgrades of varying slopes, although it becomes more difficult to compact the layer as slope steepness increases beyond 3H:1V. The CCL may range in thickness from 150 mm to 1,500 mm, depending on the application and the relevant regulatory requirements. The most common CCL thickness is 600–1,000 mm.

A wide range of clay species can be effectively used as a low-permeability barrier. Few regulatory or engineering restrictions guide the appropriate mineralogical makeup of the soil used or its physical properties. This means that a clay liner can be built using any available soils, as long as the finished product achieves the relevant hydraulic conductivity requirement, which is typically 1×10^{-9} m/sec.

For these reasons, there is no “standard” clay liner with a certain mineralogical composition and a specific range of engineering properties. The soils used to construct a CCL are often extracted from the site where the liner is to be located to minimize the cost of excavating and transporting suitable clay soils from an offsite borrow area. Thus, the mineralogy of clay liners varies significantly, relating more to local geology than engineering and regulatory requirements. In fact, very few data are available identifying the mineralogy of specific clay liners. Although the performance (hydraulic conductivity) of these liners has been exhaustively studied, their composition has been studied only occasionally (Kovach 1991; Millard 1995).

Soil-Bentonite Liners

Liners are often built in locations with unsuitably porous or rocky in situ soils, so clay soils must be brought to the project site and then placed on a prepared foundation. Instead of importing the full volume of clay soils needed for the liner, it can be more economical to import bentonite clay, which is then mixed with the existing soils. Sodium bentonite, with its ability to swell significantly when wetted, can fill large pore spaces in sandy or other well-grained soils and thus reduce permeability to a required level. The end result is a soil-bentonite liner (SBL). These liners have also variously been called “mixed blankets,” “bentonite-amended liners,” and “bentonite-enriched soils.”

SBLs are constructed in one of two ways. Bentonite can be deposited directly on the soil and tilled into it to a prescribed depth; or when more application control or a thicker liner is needed, the bentonite is mixed with soil using a pug mill. This mixture would then be placed and compacted on a prepared subgrade. Like CCLs, SBLs have also been effectively used for several decades. But with the growing ease of use and regulatory acceptance of geomembranes and geosynthetic clay liners, SBLs are not as prevalent as they were in the early and mid-1960s, 1970s, and 1980s.

Geosynthetic Clay Liners

GCLs are the newest class of clay liner; they were invented in 1982 but did not achieve commercial success until the early 1990s. A GCL is essentially a hybrid of geosynthetic materials (geotextiles and geomembranes) and sodium bentonite clay (Figure 1). A GCL uses the impressive barrier properties of sodium bentonite to form an effective hydraulic barrier in a convenient package (5–10 mm thick) that can be unrolled on a prepared subgrade. Any clay mineral could be incorporated into a GCL, but sodium bentonite has the unique ability to form a monolithic gel structure when wetted. In this form, it has a very low hydraulic conductivity (1×10^{-10} m/sec to 1×10^{-11} m/sec) and does not require mechanical compaction. Because sodium bentonite is a swelling clay, the hydration process results in very few interparticle pathways that conduct flow.

GCLs are typically used as alternatives to CCLs and are often compared to CCLs to ensure that the performance objectives for the liner system as a whole can be achieved. This comparison is known as an “equivalency” demonstration and has been the focus of much research and discussion among engineers, regulators, and GCL manufacturers.

The several varieties of GCLs all have a few common elements. First, they all contain sodium bentonite because it is the only material proven to possess the hydraulic properties needed for lining applications. Second, they all include one or more geosynthetic materials. The most common GCL configuration is a “sandwich” of bentonite and geotextiles that are laminated or needlepunched together. Other GCLs are produced with a layer of bentonite adhered to a geomembrane.

Cutoff Walls

If CCLs, SBLs, and GCLs constitute the category of horizontal clay barriers, then cutoff walls represent the category of vertical clay barriers. Cutoff walls are used almost exclusively in environmental remediation projects where it is necessary to contain a migrating subsurface contaminant plume. These barriers can also be used to control the local groundwater gradient at a contaminated site, allowing more efficient use of remedial groundwater treatment technologies.

Cutoff walls present a completely different set of practical and engineering challenges than horizontal barriers. The presence of groundwater (often contaminated), unstable soils, unfavorable terrain, and other commonly encountered obstacles and site conditions make cutoff walls difficult to build. But they are often essential to the successful remediation of a contaminated site, and much research has been performed to overcome site challenges and optimize their effectiveness.

Cutoff wall construction involves trenching into the subsol around a site to a prescribed depth, usually such that the wall can be “keyed” into a low-permeability clay strata or aquitard. “Hanging” cutoff walls, which are not keyed into such an aquitard, can be built if the contaminants of concern are less dense than water (Figure 2).

A bentonite slurry holds the trench open during construction. The slurry is denser than water and thus offsets the hydrostatic pressure on the sidewalls of the trench. The bentonite also forms a “filter cake” on the sidewalls that itself is a barrier to flow and further contributes to trench stability. Using bentonite slurry in this fashion has resulted in the name “slurry wall,” but “cutoff wall” is preferred when describing barrier applications of this construction method.

A cutoff wall is constructed with simultaneous excavation and backfilling. Excavation at one end of the trench is followed by backfilling at the opposite end. The exposed trench is always filled with bentonite slurry or backfill. This keeps the disturbed area to a minimum and optimizes the use of slurry. The nature of the backfill determines the type of cutoff wall constructed during this process.

Three types of cutoff walls contain clay: soil-bentonite (SB), cement-bentonite (CB), and soil-cement-bentonite (SCB). Many other materials can be used in cutoff walls, however, including concrete, plastic membranes, steel sheets, and porous reactive media. This discussion focuses only on those types of cutoff walls containing clay.

SB Cutoff Walls. The bentonite in an SB wall decreases the hydraulic conductivity of the backfill soil just as it does in horizontal SBLs. Soil, bentonite, and water are mixed at a predetermined ratio necessary to ensure uniform slump into the bottom of the trench while still providing low hydraulic conductivity.

Source: Spooner et al. 1985.

Figure 2. Conceptual view of (a) keyed-in and (b) hanging cutoff walls

CB Cutoff Walls. In a typical CB wall, a 2%–10% by weight bentonite-to-cement mixture is used to backfill the trench. A CB wall will possess significant compressive strength, which may be necessary to ensure the stability of nearby structures or topographical features near the construction site. The inverse relationship between strength and hydraulic conductivity means that the amount of bentonite added to the mixture must be enough to form a barrier but not so much as to excessively reduce the compressive strength of the wall.

SCB Walls. As the name of this barrier implies, an SCB wall uses soil, cement, and bentonite to achieve a certain combination of barrier and strength properties required for a specific project. One advantage of an SCB wall over a CB wall is that the excavation spoils can be incorporated into the backfill, thus reducing waste (Inquip 2004).

Clay Barrier Applications

Clay barriers are used in any application that must contain water or waste. A brief discussion of the four broad classes of clay barrier applications prefaces a presentation of detailed engineering properties of clay soils that relate to these applications.

Surface Impoundments

The term *surface impoundment* describes any structure designed to contain water: decorative ponds, reservoirs, fire ponds, sedimentation/retention basins, dams, canals, and wastewater lagoons. Even engineered wetlands would fit into this broad classification of water containment structures.

Surface impoundments are the earliest applications of clay barriers. The need to control the flow of water is among the most basic needs of an industrialized civilization, and clay soils played a critical

role in doing so long before the advent of other impervious materials. Using clay soils in engineered surface impoundments is much more recent, however. When mechanical earthmoving equipment began to replace human labor (about 1900 in the United States), the ability to shape the earth greatly improved. Manipulating soils for various engineering projects became the subject of intense focus, thus beginning the clay liner era. It is interesting to consider the difficulties that must have been present when lining projects were built around the turn of the 20th century. There were no formal soil classification systems, no standard construction practices or specifications, and, perhaps most important, no laboratory tests or test equipment to measure the hydraulic conductivity of clay soils.

The construction of a reservoir in Baltimore, Maryland, in 1908 illustrates the difficulties of these working conditions (Beatty 1912). For this reservoir, a cutoff wall was installed under the toe of a dam to prevent seepage under the dam face. The cutoff wall was composed of compacted ("rammed") clay placed in many 3-in. lifts. The water tightness of the clay layer was tested by embedding perforated pipes in the clay and then pressurizing the pipes. Visual observations of the clay wall were made to see if seepage occurred. Indeed, it was discovered that water seeped through the interlift boundaries of the clay layer, a phenomenon noted decades later by Daniel (1991). Further studies on the suitability of the clay were made by digging small pits into the surface to observe whether the water level decreased. Beatty (1912) also describes the quality control procedures in place for placement of the clay, whereby inspectors required that all lumps be "broken to the size of an orange, and all larger stones rejected."

It is clear that although clay has a long history of use as a liner, a truly engineered clay barrier did not emerge from its application in surface impoundments. The more likely origin of the engineered clay barrier is the waste containment industry.

Landfill Covers

Early municipal waste landfills were seldom installed with any kind of engineered barrier system. Municipalities located garbage dumps on the basis of convenience, close to urban centers, in old quarries or gravel pits, or on "unproductive" land such as swamps. Pre-industrial era household refuse was not likely to be especially harmful, but solid and liquid wastes from industrial sources were proven in the 1960s and 1970s to be a significant cause of long-term environmental contamination. Modern environmental legislation forced the closure of these dump sites, and new scrutiny was applied to developing suitable barriers to the inflow of precipitation. The era of the engineered clay liner had begun.

Placing a clay layer on an existing landfill serves several functions. Most important, it limits the infiltration of precipitation that would otherwise percolate into the waste mass and then out the bottom of the dump into groundwater. The clay cap also contains gases generated as organic matter decomposes in the waste. In so doing, the clay reduces offensive odors, which are a common nuisance to nearby residents. Finally, the clay is a buffer between environmental receptors (plants, animals, and humans) and the potentially harmful waste itself.

Landfill Liners

Inadequate containment of landfilled waste causes environmental problems that the U.S. Environmental Protection Agency (EPA) Superfund cleanup program is still working to resolve. Thousands of national and state-led cleanups of old landfills and dump sites were completed over the past 25 years, many of which consisted of placing some form of cap over the waste.

With the hindsight provided by these contaminated sites, more research was undertaken to ensure that new landfills were designed

to minimize the threat of leakage. Governments instituted various measures, such as banning the disposal of liquid wastes, imposing siting restrictions, and restricting the disposal of hazardous materials. Additional work was done to develop liner performance requirements in this newfound era of environmental responsibility.

EPA's report to Congress in 1974 concluded that existing waste management practices in the United States at the time were "generally inadequate" and that better control of the wastes was necessary to protect public health and the environment. Congress agreed and passed the Resource Conservation and Recovery Act of 1976, authorizing EPA to establish waste management controls and regulations (Haxo et al. 1984). Research into the effectiveness, compatibility, and durability of lining materials accelerated to improve waste management practices.

Knowledge of clay liners had accumulated over several decades of experience in water containment applications such as dams, reservoirs, and canals. This experience was not wholly relevant to waste containment, where possible chemical interactions with the liner must be considered and where seepage from the liner is potentially hazardous. Therefore, new information and research were needed to ascertain the effectiveness of clay liners in waste containment applications.

One of the first and most important research programs evaluating the compatibility of clay liners with chemical contaminants was summarized in an EPA document, *Liner Material Exposed to Hazardous and Toxic Wastes* (Haxo et al. 1984). This report offered a comprehensive investigation into the performance of both clay and synthetic membrane liners (new at the time) after long-term exposure to both real and laboratory-prepared liquid wastes. The study, performed from February 1975 through July 1983, found a wide range of performance variations depending on the materials and wastes used. This report set the stage for even more research into the use of clay barriers for waste containment, discussed later in this chapter.

Mining Applications

Clay liners are used in many types of mining applications, including stormwater detention, process water collection, heap leach pad lining, and final closure or remedial closure. The function of the clay in these mining projects is the same for the other applications described herein: containment of water and leachate. The only difference is that the leachate to be contained in mining projects has a much different chemistry than that in waste containment.

Heap leaching is a mineral processing technology in which large piles of rock are percolated with chemical solutions that extract valuable minerals. The largest heap-leaching operations involve copper mining, where copper-bearing rock is flushed with a weak sulfuric acid solution. This solution dissolves the copper from the mineral and is carried in the leachate to a collection system resting on top of a liner. An electrowinning process extracts copper from the solution, and the leachate is then recirculated to the ore pile. Gold is extracted in much the same fashion, except that the leaching solution contains low concentrations of cyanide. The hazardous solutions used in heap leaching require a robust liner system. Leach pad lining practices vary worldwide, but commonly a geomembrane (such as high-density polyethylene [HDPE] or polyvinyl chloride [PVC]) is the primary liner and a clay barrier may be used as the secondary liner.

ENGINEERING PROPERTIES OF CLAYS FOR BARRIER APPLICATIONS

Civil engineers evaluate several different properties to assess a soil's suitability as a liner material. It is rare that a candidate soil

will possess superior attributes across the complete spectrum of desirable properties; in fact, usually any one desirable attribute is offset by one that is undesirable. For example, a highly plastic clay that possesses beneficial strain behavior is not likely to be sufficiently compactable. The engineer must identify an acceptable "window" of properties that allow a clay soil to function as a barrier. This design approach ensures that performance requirements can be achieved yet still allow the variability that is inherent with natural soil materials.

Hydraulic Conductivity

Hydraulic conductivity measures the intrinsic capability of a soil to convey water. This term is often used interchangeably with *permeability*, although, in the strictest sense, permeability applies to all liquids inclusive of organic chemicals and aqueous chemical solutions. This distinction is rarely applied in engineering parlance, and so this chapter uses hydraulic conductivity and permeability interchangeably.

Hydraulic conductivity is by far the most commonly specified and required property for a soil liner. In fact, permeability and thickness are often the only properties ever specified or required. Taken together, permeability and thickness can be used to theoretically estimate the total amount of flow (leakage) expected for a saturated soil layer under a specified hydraulic head pressure.

During the period from 1855 to 1856, Henry Darcy worked to identify the relationship between flow and permeability. Darcy's law resulted from a series of experiments in which he subjected a column of soil to a constant hydraulic force and measured the water flow rate through the soil (Figure 3). The flow rate was found to be directly proportional to both the hydraulic head and a numerical constant he designated as "*k*." The value of *k*, in units of meters per second or centimeters per second, has become the defacto indicator for a soil's relative ability to transmit water. Mathematically, Darcy's law is:

$$Q = kA(\Delta h/L) \quad (1)$$

where

- Q = volumetric flow rate (cu m/sec)
- k = hydraulic conductivity (m/sec)
- A = flow area perpendicular to L (sq m)
- h = hydraulic head (m)
- L = flow path length (m)

Equation (1) can be simplified by noting that the term $\Delta h/L$ is actually the change in hydraulic head from the top to the bottom of the liner. Assuming that the liner leaks into an unsaturated zone, the head pressure at the bottom of the liner is zero and $\Delta h/L$ becomes equal to the *hydraulic gradient*, which is $(h + L)/L$. The gradient is usually designated as *i*, and the lined area A can be made equal to 1 sq m to obtain a flow rate per unit area (q). Thus, Darcy's law is reduced to $q = ki$. For example, for a clay liner with a permeability of 1×10^{-9} m/sec and a thickness of 0.6 m, leakage at a head of 3 m would be calculated by applying the simplified version of Darcy's law,

$$q = ki, \quad (2)$$

where

- q = unit flow rate (cu m/sec)
- k = hydraulic conductivity (m/sec) = 1×10^{-9} m/sec
- i = hydraulic gradient = $(h + L)/L = (3 \text{ m} + 0.6 \text{ m})/0.6 \text{ m} = 6$.

Therefore,

$$q = (1 \times 10^{-9} \text{ m/sec})(6) = 6 \times 10^{-9} \text{ cu m/sq m/sec or } 5,184 \text{ L/ha/day.}$$

^a Note the trend of decreasing permeability with decreasing grain size.

As would be expected, soils with smaller particles have a lower permeability (they will allow less flow) than granular soils. Table 1 lists soil types and their typical permeability values. Only those soils with some clay fraction achieve the permeability values required to be considered suitable for a liner (as defined by a permeability value of 1×10^{-9} m/sec or lower). Small particles create a "tortuous path" of interconnected pores through which water passes only very slowly. This results in a low permeability value if the soil is placed and compacted correctly.

Some clay soils can achieve permeability requirements more easily than others. The relative ability of a soil to be compacted as a functional liner depends on a combination of many properties, including moisture content, density, and of course particle size. The effects of these other variables are discussed in the section on Compacted Clay Liners and Soil-Bentonite Liners in this chapter.

Particle-Size Distribution

All naturally occurring soils contain a range of particle sizes. Soils used for liners have a significant fraction of very small particles, or

Courtesy of CETCO.

Figure 4. Schematic of moisture values relating to the Atterberg limits of soil

"fines," that reduce the ability of the liner to transmit flow. The fines content of a soil is usually defined as the weight fraction of a sample having a particle size of less than 0.075 mm (corresponding to the amount passing a 200-mesh sieve). With a preponderance of small particles, the permeability may be low enough for the soil to function as a liner. This means that the particle size of the remaining 70% of the soil can vary widely and even include stone or gravel particles without affecting liner performance. Shakoor and Cook (1990) found that it was possible to achieve a permeability value approaching 1×10^{-9} m/sec even when the stone fraction in a soil was 50%. Beyond this point, however, permeability values increased several orders of magnitude. In practice, this means that there can be tremendous variability in particle size for a soil liner, but it can still function effectively as long as the fines content is 30% or greater (Benson, Zhai, and Wang 1994).

There will always be uncertainties relating to the maximum allowable particle size in a clay liner. Although a single large stone or rock may not lower overall performance, the presence of multiple large rocks most likely will increase its permeability. Therefore, the maximum particle size is often recommended not to exceed 25–50 mm (Daniel 1990). Screening the soil before placement controls particle size but this adds cost to the project and can be a source of controversy between quality control personnel and the contractor.

The grain size distribution of a soil determines its classification. In the United States, the Unified Soil Classification System (USCS) predominates, although there are dozens of different classification schemes worldwide. This system, whose nomenclature is used in Table 1, defines soils by particle size, gradation, plasticity, and compressibility. Geotechnical engineers use the USCS most often because these parameters have a strong relationship to the properties of soil structures such as dams, embankments, and liners. Other classification systems, derived from formation mechanisms or geographical location, are not descriptive of engineering considerations.

Another advantage of the USCS is its ability to classify soils through visual observation, with added laboratory testing for confirmation and complete description of the soil. When constructing a liner, it is helpful to have a third-party quality assurance inspector (one experienced in the classification process) monitor soil placement activities to determine if the soil is within the range of classifications that allow for the construction of an adequate hydraulic barrier.

Atterberg Limits

The Atterberg limits describe transition points in the consistency of a given soil throughout its full range of moisture content from zero to complete saturation (Figure 4). The plastic limit (PL) is the boundary moisture content at which a soil transitions from a plastic

Courtesy of CETCO.

Figure 5. Free swell (a) and fluid loss (b) testing of bentonite

to a nonplastic and noncohesive state. The liquid limit (LL) is the moisture content at which the soil transitions from a plastic, cohesive mass to a viscous fluid. The difference between the LL and the PL is known as the plasticity index (PI), which defines the complete moisture range over which the soil is considered to be in a plastic state.

In a general sense, the larger the PI, the more suitable the soil as a barrier. This is because the PI is really an indirect measure of particle size. Clay particles can absorb water, thus imparting plasticity. Moreover, a plastic soil can accommodate tensile strain better than a nonplastic soil. There is a trade-off, however, between plasticity and compaction. A soil with an extremely high PI may not be compactable to the extent needed to make it structurally sound and to achieve the density needed for low permeability. Benson, Zhai, and Wang (1994) evaluated PI data for 67 landfills in North America and found that acceptable permeability values were achieved when the PI exceeded 7. The lowest permeabilities were achieved with the PI ranging from 10 to 30.

Moisture Content and Density

The most important performance parameter for the completed clay liner is its permeability. Many researchers (Rogowski 1990; Shaktour et al. 1996; Benson, Daniel, and Boutwell 1999; Alba et al. 2000) have shown that the in situ permeability of clay liners can be orders of magnitude higher than the design value. These results demonstrate the need for a better understanding of the soil properties and accompanying construction techniques to achieve acceptable field performance.

The moisture content and the compacted density of a soil exert primary influence on its hydraulic properties. Moisture, when added to a dry soil, facilitates compaction by lubricating adjacent particles, allowing them to slide against each other into a tighter arrangement. As a result, the density of the soil increases, its porosity decreases, and its in situ permeability decreases. Proctor's work in the 1930s laid the groundwork for understanding soil moisture–density relationships. Mitchell, Hooper, and Campanella (1965) demonstrated how compactive effort affected clay soil permeability. Finally, in 1990, Daniel and Benson performed landmark research to extend these relationships to predict permeability. The most important aspect of this work was the introduction of the concept of an “acceptable zone” of moisture contents and densities that could be measured in the field and would relate to the ultimate performance criterion of permeability. The discussions of design later in this chapter give more information on this concept.

Bentonite Free Swell and Filtrate Loss

Sodium bentonite as an admixture to porous soils improves their workability and decreases their permeability. If the bentonite is effective in filling voids in such soils, bentonite admixtures can be very effective liners. Bentonite also is the barrier component of GCLs. The primary properties of bentonite that affect its performance in both SBLs and GCLs are free swell and filtrate loss (Figure 5).

A free swell test measures the ability of bentonite to swell in an unconfined state. In this test, 2 g of powdered bentonite are slowly distributed into a graduated cylinder filled with deionized water. After 16 hr, the interface between the swollen clay and water is recorded as the free swell. For bentonite used as an admixture, the typical required value is 16 mL; for bentonite used in GCLs, the typical required value is 24 mL.

A fluid loss (or filtrate loss) test comes closer to evaluating a clay's ability to form a hydraulic barrier, although the oil exploration industry developed it to evaluate bentonite-based drilling fluids. In drilling applications, bentonite mixes with water to form a viscous slurry that suspends drill cuttings, lubricates the drill bit, and forms a protective coating on the interior of the borehole. This coating prevents water from entering the borehole and thus prevents its collapse during drilling operations. The fluid loss test mimics the ability of the bentonite to form this layer. A bentonite slurry is subjected to a pressure of 690 kPa (100 psi) and then forced through a filter paper. The fluid loss of the clay is the direct measure of the volume of water that percolates through the filter cake. A high-quality bentonite will form a low-permeability coating and will possess a low filtrate loss. In oil exploration, a value of 15 mL is desired. In GCLs, the industry has established a baseline requirement of 18 mL. The fluid loss test is also important in cutoff wall applications, where a bentonite slurry supports the open trench (see sections on quality control in this chapter).

The origin of these free swell and fluid loss requirements is somewhat uncertain. Olsta, Daniel, and Chung (2004) evaluated bentonite clays of varying free swell and fluid loss values to determine what relationships, if any, they had with respect to permeability.

Interestingly, there was very little correlation between free swell and permeability, especially for free swell values exceeding 18 mL. This value appears to be a threshold above which the bentonite is capable of hydrating into a monolithic mass with few flow pathways. There is a better correlation between fluid loss and permeability; a fluid loss of 18 mL is the upper limit for GCLs required to possess a permeability of 5×10^{-11} m/s. Still, there was considerable scatter in these data, indicating that other clay properties may affect permeability test values.

Although both tests are useful in assessing the quality of the bentonite for a GCL or SBL, neither test alone is a reliable indicator of bentonite's potential as a barrier. There is still a need for a short-term bentonite test that can serve as an indicator for GCL permeability tests, which can take as much as a week to perform.

Contaminant Transport

Clay barriers are used extensively in waste containment applications and therefore should effectively mitigate the flow of waste materials, not just clean water. Landfill leachate is the liquid formed when water percolates through waste. Chemicals and particles in the leachate may eventually contact the liner system, with the potential to cause degradation. In wastewater containment applications, municipal or industrial process water may also contain deleterious chemicals that can affect the liner. Understanding contaminant transport is necessary when evaluating clay liner materials.

Advection

Advection refers to the direct mass flux of contaminants contained in a waste liquid. Advection is quantified by multiplying the flow rate (flux) by the contaminant concentration. Thus, the permeability and flux of the clay barrier completely control advective contaminant flow. Although it is a simple matter to calculate the amount of a specific contaminant being released from a clay barrier, actual flux values are likely to differ significantly from advective flux calculations. The effects of concentration variation, contaminant attenuation, soil liner saturation, and diffusion all complicate the task of modeling contaminant transport.

Goldman's (1988) report for the EPA is an authoritative source for detailed information on the permeability behavior of clay liners with many chemical contaminants. The results of many different studies were assembled to demonstrate that clay soils are affected to varying degrees by different chemicals. It was also found that various clay-chemical interactions can influence permeability and thus advective transport. For example, a chemical can modify the soil "fabric" (its arrangement of particles) by dispersion and flocculation. A chemical that disperses the clay particles (such as sodium in the presence of montmorillonite) can decrease permeability. A chemical that flocculates or collapses the clay particles (such as calcium in the presence of montmorillonite) can increase pore size and increase contaminant flux significantly.

Other chemicals such as strong acids or bases can literally dissolve the clay fabric and thus increase its permeability. Finally, pores can be physically blocked by precipitated metals or microorganisms, leading to a beneficial decrease in permeability.

Diffusion

Diffusion is the movement of contaminants through a liner owing to the presence of a concentration gradient. Advection and diffusion can occur together, but they are totally different transport mechanisms. Whereas advection relies on a hydraulic gradient, diffusion depends on a concentration gradient. Net movement of contaminants will be from areas of higher concentration (above the liner) to

Table 2. Comparison of contaminant transport mechanisms

Feature	Advection	Diffusion
Governing equation	Darcy's law $q = k i C$	Fick's law $q = D^* n (\Delta C/T)$
Transport driving force	Hydraulic gradient (i)	Concentration gradient ($\Delta C/T$)
Intrinsic soil property	Permeability (k)	Coefficient of diffusion (D^*)
Limiting assumption	Saturation of liner	Saturation of liner

areas of lower concentration (below the liner). Table 2 gives a conceptual comparison of these mechanisms.

It is extremely difficult to quantify diffusion, partly because every soil has a unique coefficient of diffusion for each contaminant of concern. The time dependency of the diffusion process is another complicating factor. A great deal of research has been performed to understand how diffusion occurs and to assess its significance as a contaminant transport mechanism. Various researchers have adapted Fick's law to predict contaminant flux. While the means and methods of this research vary, a generally supported conclusion has been that diffusion can be a significant transport mechanism, especially for thin barriers such as plastic geomembranes and GCLs. For CCLs, advection appears to be the dominant transport mechanism when the in situ permeability of the clay is less than 1×10^{-9} m/sec. Refer to works by Brown and Thomas (1998); Foote, Benson, and Edil (1999); Katsumi et al. (2001); Kim, Edil, and Park (2001); and Foote (2002) for detailed discussions of these issues.

Attenuation

Attenuation refers to the ability of a material to absorb or otherwise impede the movement of contaminants. Because clays have a high cation-exchange capacity (CEC) relative to other soils, it has been theorized that clay barriers can serve not only as physical barriers but also as "treatment" media that actively remove contaminants as liquids flow through them.

Early research by Griffin and Shimp (1978) performed when clay barriers were the only widely available option for waste containment focused on known contaminants, such as dissolved metals, in municipal landfill leachates. Column studies revealed that most clays could moderately attenuate K, NH_4 , Mg, Si, and Fe. The same study found that the clays strongly attenuated heavy metals such as Pb, Cd, Hg, and Zn, but organics were not attenuated. Edil, Park, and Heim (1993) also found that volatile organic compounds such as methylene chloride and trichloroethylene were not significantly attenuated. The pH of the leachate and the effects of other solutes in the leachate also altered the attenuation capabilities of the liner materials.

Thornton, Lerner, and Tellam (2001) found that heavy metals were attenuated by sorption and precipitation of metal sulfide and carbonate compounds near the top of the liner. Adequate reserves of sulfates and carbonates are needed for these processes to occur. Ammonium was attenuated by ion exchange but was detected in effluent flow when the exchange capacity was exhausted. They also found that some metals may not be attenuated if they occur as stable complexes with organics in the leachate.

In general, the mechanisms of advection, diffusion, and attenuation are potentially important contaminant transport issues, yet it is difficult to make any general statements regarding the predicted behavior of a clay liner. The type and concentrations

of contaminants, the surrounding chemical environment, the interrelationships of other contaminants, and the unique composition and construction of the clay barrier itself all combine to create a unique “signature” related to its performance in contaminated liquids. For this reason, past research is helpful in understanding the mechanisms by which clays can be affected by chemicals, but it certainly is not predictive with respect to a specific clay liner and specific chemicals of concern.

ENVIRONMENTAL REGULATIONS FOR CLAY BARRIERS

Like clay soils themselves, the regulatory environment for clay liners varies significantly from state to state within the United States and from country to country around the world. Although there are common prescriptive clay liner standards, the requirements set forth by individual regulatory entities vary. The concerns of regulatory personnel, past experience with clay barriers, and the geography within a regulated region all combine to demand a project-specific approach to liner design and construction.

U.S. National Regulations

National rules for clay liners in the United States, which were promulgated by the EPA, exist only for landfill bottom liners and final covers. States regulate clay liners used in other facilities (water and wastewater storage lagoons, etc.). U.S. landfills can be used for the disposal of either “solid” (nonhazardous municipal) or hazardous waste. The rules for the containment of solid waste are understandably less stringent than those applicable to hazardous waste disposal facilities. In both cases, however, the clay liner requirements are similar, varying only in the thickness required for each type of facility.

Solid Waste Landfills

The national regulations for solid waste landfills appear in 40 CFR 258 (also known as Subtitle D; EPA 1988). EPA provides the states with considerable latitude in implementing these rules because they are risk based. This means that a landfill is permitted only when it will not exceed groundwater quality criteria at its boundaries. These criteria are drinking water standards for which numerical limits are derived from toxicological studies designed to identify the relative risk of exposure to various contaminants. Thus, the primary intent of 40 CFR 258 is not to provide detailed landfill design instructions, only to ensure that human health is protected regardless of the design selected. In this way, EPA allows the use of any type of liner system if it can be shown to protect groundwater.

Recognizing that there may be insufficient data to develop a detailed design based on this approach, EPA offers an optional approach in which specific liner design criteria are listed. 40 CFR 258.40(a)(2) indicates that a composite liner, consisting of a geomembrane and a clay layer, is an acceptable alternative to the risk-based design approach. According to this section, the clay component of the composite liner must be 2 ft (600 mm) thick with a permeability not to exceed 1×10^{-9} m/sec (EPA 1988). For a final cover on a solid waste landfill, 40 CFR 258.60(1) requires a soil cover less than or equal to the permeability of the bottom liner, but at least 450 mm thick with a permeability not to exceed 1×10^{-7} m/sec. Interestingly, these are the only prescriptive performance standards for clay liners for any application regulated by EPA.

As might be expected, states that administer their own solid waste disposal programs prefer these specific prescriptive standards. Although the need for a composite liner system in, for example, Nevada, might be less than that in Florida, regulatory entities prefer to adopt the prescriptive approach to guarantee their compliance with national regulations. This means that any liner system not

specifically meeting the prescriptive standard must be evaluated as an “alternative” design and therefore subject to careful scrutiny as a potential replacement for the geomembrane and clay composite system mentioned in Subtitle D.

Hazardous Waste Landfills

The EPA regulations for hazardous waste landfills are codified in 40 CFR 256 (Subtitle C; EPA 1988), with liner criteria specified in Section 264.301(c)(1)(B). The liner must be at least 900 mm thick with a maximum permeability of 1×10^{-9} m/sec. For final covers, the regulations in Section 264.310(a)(5) mirror the solid waste regulations with respect to thickness and permeability requirements. Final covers on hazardous waste landfills must contain a compacted soil liner with a thickness of 900 mm and a permeability no greater than 1×10^{-9} m/sec.

Furthermore, hazardous waste landfills require a “double composite” system in which two independent composite liners are installed with a leak detection system between them. Interestingly, some states (Florida, Michigan, and New York) have also adopted this rigorous standard for their solid waste landfills.

Thickness Requirements

The default soil liner thickness is 2–3 ft, or 600–900 mm. In almost any country or state, these thickness requirements rarely differ. What is the rationale behind a thickness requirement of 600–900 mm? Although its origin is unclear, the requirement has been in existence at the state level since the 1970s. It was not until many years later that research verified the adequacy of this thickness range.

Benson and Daniel (1993a, 1993b) researched the hydraulic performance of clay liners of varying thicknesses. They concluded that there is little improvement in performance when the thickness of a clay liner is increased beyond 600–900 mm (4–6 lifts). Because clay liners are installed in lifts that are 250–300 mm thick, the performance of the liner relates to the performance of the lifts rather than the liner as one continuous layer. Benson and Daniel found that four to six lifts provide a liner with the redundancy needed to minimize the potential for preferential flow pathways to penetrate through the entire liner. In other words, there is a point of diminishing returns when landfill liners are more than 900 mm thick, and the performance benefits seldom justify the expense of building a thicker soil liner. Thus it appears there is sound technical justification for the currently adopted liner thickness regulations, even if the thickness rules predated the supporting data.

Hydraulic Conductivity Requirements

In almost all U.S. and international regulations, the hydraulic conductivity requirement for a clay liner is 1×10^{-9} m/sec. Although occasional exceptions to this value are based on environmental risk levels specific to different locations and applications, it is clear that the generally acceptable clay liner must achieve a permeability of 1×10^{-9} m/sec in both laboratory and field quality control (QC) testing.

There is no known precedent for the universal selection and adoption of this value. In all likelihood, a permeability of 1×10^{-9} m/sec represents a performance standard that is a compromise between achieving maximum containment and achieving reasonable cost and construction feasibility. In other words, higher permeability requirements (such as 1×10^{-8} m/sec) could result in unacceptable levels of environmental contamination, whereas lower requirements (such as 1×10^{-10} m/sec) may not be possible to achieve with many soils and would create undue technical and

financial burdens associated with identifying clay materials that could achieve this value.

GCLs in National Regulations

Although GCLs constitute a large and growing fraction of landfill liner and cover systems built in the United States, they are not mentioned in any Subtitle C or D rules, because the rules were written long before GCLs were commercialized and used in landfills. The first landfill use of a GCL was in 1985 when Claymax was installed into an industrial waste disposal cell in a Chicago, Illinois, landfill. The GCL was sandwiched between two geomembranes and served as a secondary component of the liner system that was not required under Illinois law at the time. GCLs were then installed in 1986 in two municipal landfills in Pennsylvania, again to supplement, not replace, the clay component of the liner system required by law. Other than these uses, GCLs did not gain widespread commercial use until 1992–1994, about 1 year after Subtitle D was finally issued.

Because EPA rules do not cover GCLs, a great deal of research has compared them to the clay prescriptive standard. If it can be shown that a GCL is equivalent to the CCL, then it may be approved for use. Koerner and Daniel (1993) authored a comprehensive equivalency review of GCLs and CCLs. The review covered all major design, performance, and construction issues that might be of concern to regulators tasked with evaluating whether a GCL could be considered “equivalent” to a CCL (and thus acceptable for use in a Subtitle D-compliant landfill liner or cover system).

They concluded that GCLs were indeed equivalent and often superior to CCLs in most aspects of comparison. Using this and other equivalency concepts, GCLs have emerged not only as acceptable but often as preferred alternatives to CCLs, as is explained in the section on Geosynthetic Clay Liners in this chapter.

State Regulations

For landfills, liner systems are regulated at the state level assuming that the state solid waste management program is in general compliance with the national rules in Subtitle C and D. In many cases, the state regulations are virtually identical to the national regulations already discussed. Many states, however, have adopted more or less stringent liner design rules based on their specific geographical situations. States in humid climates have more stringent liner regulations than those in arid climates. Florida, for example, requires a double composite liner system containing two geomembranes and two clay components. Wyoming, on the other hand, requires only a single liner system consisting of a CCL, a GCL, or a geomembrane. This is exactly what EPA intended in promulgating risk-based standards in stead of an overall requirement that might place an unreasonable burden on some states or may not be sufficiently protective of human health in others.

States also have liner regulations pertaining to wastewater storage lagoons. The most widely recognized regulations are adopted from the Great Lakes–Upper Mississippi River Board of State and Provincial Public Health and Environmental Managers (1997). This group developed the so-called “ten-state standard” that contains clay liner design requirements for wastewater storage facilities. The ten-state standard is expressed in terms of a maximum leakage rate of 500 gal/acre/day, or 4,695 L/ha/day, at a depth of 6 ft (1.8 m). Assuming a thickness of 600 mm, this equates to a permeability of 1.8×10^{-9} m/sec, which is slightly higher than the de facto standard appearing in other regulations.

Not all states have adopted this standard. As with landfills, states developed wide-ranging liner performance criteria depending on specific issues relevant to each state. It is beyond the scope of this chapter to list all the different state level rules for such facilities.

Other Regulations

The United States has influenced liner system design and regulation worldwide. Although countries vary significantly in clay liner requirements, many adopted the EPA’s prescriptive standard liner system. Koerner and Koerner (1999) summarize worldwide landfill liner system regulations. In general, more developed countries have more stringent regulations than those that are less developed.

The European Union adopted a clay liner requirement of 1 m thickness and 1×10^{-9} m/sec permeability; this rule applies to both landfill bottom liners and landfill covers (CEC 1999). For hazardous waste landfill liners, the thickness requirement is 5 m and the same permeability value of 1×10^{-9} m/sec.

COMPACTED CLAY LINERS AND SOIL-BENTONITE LINERS

Although CCLs and SBLs are constructed in different ways, the general design issues discussed herein are applicable to both types of liners.

Design

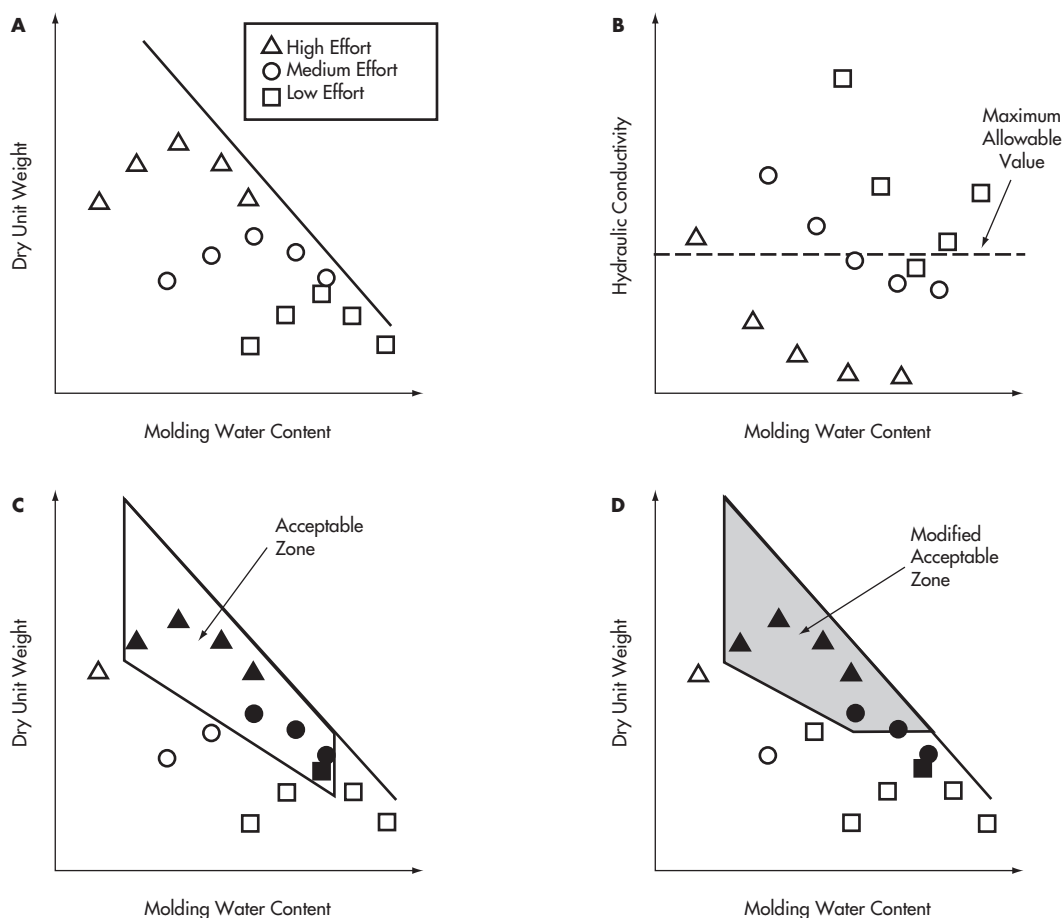

The design of a clay liner requires detailed knowledge of the soil properties such that a technically appropriate specification can be written. A designer is interested primarily in moisture-density relationships, water balance models, time of travel, and slope stability.

Moisture–Density Relationships

The hydraulic performance of a clay liner depends greatly on properly determining the relationship between soil moisture, density, and permeability. The designer must identify acceptable clay soil sources for the project. Determining whether these sources contain soils that can achieve the required permeability values is best accomplished with a four-step process, as described in Daniel and Benson (1990):

1. Obtain representative samples of the candidate soils and compact them in the laboratory using standard, modified, and reduced effort to achieve compaction curves (plots of density versus moisture content), as shown in Figure 6(a).
2. Perform permeability tests on the samples and plot the resulting permeability versus moisture content. Also plot the maximum acceptable permeability (typically 1×10^{-9} m/sec) to distinguish between acceptable and unacceptable samples, as shown in Figure 6(b).
3. Highlight all the data points with “acceptable” permeability values (falling below the permeability pass/fail line from step 2) on the plot from step 1. Draw an “acceptable zone” on this plot, with the zero air voids curve as the outer border and the acceptable permeability data as the inner border, as shown in Figure 6(c).2
4. Modify the acceptable zone, as shown in Figure 6(d), to account for other design criteria such as realistic water content and shear strength. These are project-specific modifications that are made to derive a single acceptable zone for the soil in question.

Using this four-step procedure, a designer can identify the range of acceptable moisture and density values that must be achieved in the field to obtain the required permeability value. This information is used not only to qualify candidate soils but also to facilitate the construction quality control (CQC) and construction quality assurance (CQA) processes. Moisture and density can be measured rapidly and inexpensively in the field, whereas permeability tests are slow and relatively expensive. The moisture and density data then can be used to ensure maximum probability that the ultimate performance criterion—permeability—will be reliably achieved.

Water Balance Models

Mathematical water balance models are often used to demonstrate that the liner system, consisting of multiple layers of soils and geosynthetics, will meet applicable regulatory performance criteria and will not allow harmful levels of contaminants to escape a waste containment facility. Many different models are available, but the most popular and relevant model is known as the hydrologic evaluation of landfill performance (HELP). The HELP model is actually a compilation of several smaller models that simulate precipitation, runoff, percolation through various soil layers, and ultimately the amount of liquids that penetrate into or through a landfill system (Figure 7). For CCLs and GCLs, the model uses Darcy's law to calculate leakage performance (Schroeder et al. 1994).

Designers use the HELP model to determine whether a proposed or existing landfill could allow enough leachate to flow into and contaminate groundwater. If the modeling results are unfavorable, the designer can alter various input parameters such as increasing the slope of the landfill final cover, adding a barrier layer, or decreasing the spacing of leachate collection drains. Although the simulation requires numerous simplifying assumptions, the HELP model is a valuable tool to the designer because it demonstrates how various landfill design parameters can ultimately influence its environmental performance.

Figure 7. Conceptual schematic of the HELP model

Time of Travel

Theoretically, a clay liner behaves as a perfectly monolithic barrier with uniform hydraulic characteristics from top to bottom (the "plug flow" concept). This is seldom the case, as is discussed in the section on Performance of Clay Barriers in this chapter. It still may be useful to the designer, however, to evaluate CCLs in terms of

how long they will ideally contain a leachate of concern. Assuming that the liner is perfectly constructed, it will not allow contaminants to be released until the leachate front progresses from the top of the liner to the bottom. Various analytical methods have been proposed for estimating this time as a means to justify the design life of a waste containment facility (Horton, Thompson, and McBride 1988; Goode 1990; Benson and Charbeneau 1991), but the basic concept of travel time involves knowledge of the soil's permeability and *effective porosity*. Effective porosity is the fraction of total porosity that is capable of conducting flow. This is a difficult parameter to measure and renders accurate time of travel estimates difficult. Moreover, with real-world construction problems such as clods and interlift flow zones influencing flow (refer to Performance of Clay Barriers section in this chapter), the time of travel calculation is not as relevant as once believed.

Slope Stability

Sloping surfaces, whether they are lined with a CCL, a GCL, or some combination of natural and synthetic materials, must be proven to be stable. Assessing the stability of a lined slope is perhaps the designer's greatest challenge because it requires knowledge of the materials of construction, testing methods, and stability modeling. Many methods exist for calculating the stability of sloping liner systems, ranging from simplified sliding-block analyses to sophisticated finite element analyses. There is no single "best" analytical method; the most appropriate method depends on the type of liner system, the type of forces to which it may be exposed, and the relative skill and expertise of the designer. The reader is referred to works by Koerner (1994) for a more detailed discussion of the various techniques that can be used in assessing slope stability.

With respect to CCLs and GCLs, the designer is interested in measuring the shear strength of the clay internally as well as the strength of the interfaces between the liner and adjoining materials. With this information, rational analyses can be made to determine overall stability under the normal and shear loads expected for the system. Internal shear strength refers to the strength of the clay itself and whether interparticle interactions are sufficient to resist movement when shear stress is applied. Compacted clays are usually fairly strong in this regard, although "fat" clays with high moisture contents must be evaluated carefully. GCLs, with hydrated bentonite, may have very low internal shear strength unless the GCL itself is reinforced. Designers should be careful to consider the internal strength of a GCL whenever it is proposed for use on slopes.

The interface between the clay liner and adjacent materials is another potential failure plane. For example, a smooth geomembrane placed on a smooth, compacted clay surface constitutes a low-strength interface that presents considerable limitations for designers seeking to maximize slope steepness. By assessing the strength of all relevant interfaces in a liner system, the designer can identify the weakest interface and propose alternative materials that may be needed to demonstrate stability with an acceptable factor of safety.

Construction

After the designer identifies proper materials, the field performance of a clay barrier depends on the quality of its construction. Several decades of experience, research, and trial and error have led to knowledge of which construction variables influence performance and how to manage these variables in the most favorable way possible.

Equipment Requirements

Because the success of a compacted clay barrier depends on achieving the proper level of compaction, a fundamental require-

ment for proper construction is heavy compaction equipment. Daniel (1990) recommends compactors with a minimum weight of 15,000–20,000 kg (30,000–40,000 lb) equipped with footed rollers whose foot length is at least 20 cm (7.5 in.). The combination of high weight and footed rollers produces a "kneading" action that delivers high compactive energy to the soil and promotes bonding between individual lifts of the liner.

Even with these parameters specified, adequate compaction still may not be achieved unless the compactor makes a minimum number of passes over the soil. Daniel recommends at least six passes to achieve uniform compaction and density. Multiple passes also break up clods that can cause excessive flow through the liner.

Moisture Control

The acceptable zone of moisture and density determined in the design phase must be maintained consistently during the construction process. Water must be added to the soil (especially for a bentonite-admixed soil) before compaction. This is accomplished using a water truck equipped with a spray bar that can pass over each lift of precompacted soil.

Physical Processing

Depending on the quality of the soil, a screening system may be necessary to remove stones larger than the design requirements (typically 50 mm). A suitable "borrow" soil would require no further processing except where bentonite is used as an admixture. In this case, bentonite can be added in one of two ways. The simplest method, suitable for smaller projects with thin liners (<300 mm), is to place the bentonite on the surface of the subgrade and blend it with the soil using a tiller. Water is added to the SB mixture before compaction. The second method is to use a pug mill (Figure 8) to blend the soil and the bentonite together continuously. The mixture is then delivered in trucks to the working area where it is placed, spread to the specified loose lift thickness, and compacted.

Quality Control

The construction process must be continually monitored to ensure that the CCL or SBL meets the applicable permeability requirement. A properly engineered liner construction project will have a comprehensive CQC and CQA program that includes third-party inspection and testing, as described in Table 3.

The QC program should also contain provisions to deal with a failing test result, and the typical procedure in such instances is to retest the sample. If another failure results, the area from which the sample was obtained is reworked, recompacted, and resampled until passing results are achieved.

To verify the overall adequacy of the design and construction procedures intended for the liner, a test pad is often specified. A test pad is a small section of liner built specifically for testing. If passing results are obtained from the test pad, it can be presumed that the project can continue without any modification in materials or methods.

Economics and Market Trends

It is difficult, if not impossible, to make any conclusive statements regarding the economics and market conditions of clay liner construction. Based on the author's experience and market knowledge in the United States, Europe, and Asia, the following tentative statements can be offered as a general assessment of the clay liner market:

- It is conservatively estimated that at least 500 engineered landfill liners are built in the United States each year, and that at least double this number (1,000) clay liners are built for

Courtesy of CETCO.

Figure 8. Trailer-mounted pug mill (a) and close-up view of mixing blades (b) for combining bentonite with screened soil

ponds and lagoons. There is no way to verify the accuracy of these estimates, and no information is available on the world size of the highly fragmented clay liner market.

- The typical installed cost for a CCL with a thickness of 600 mm is \$4.50/sq m to \$5.00/sq m. The cost of a CCL varies significantly by region, based on materials availability, land costs, hauling costs, labor rates, and professional services. A CCL installed in the Northeast and West Coast are as of the United States would be more expensive than this range, whereas the same liner installed in the Midwest and Southeast would likely be less than this range.
- As GCLs become more commonly accepted alternatives to CCLs, the number of CCLs constructed each year will decrease, especially in waste containment applications (landfill bottom liners and covers). CCLs are typically more economical than GCLs only when clay soil is located at the project site.
- SBLs represent a small fraction, less than 5%, of all clay liner systems constructed worldwide.
- For facilities with engineered liner systems, QC costs are approximately \$250/ha.

This information is based on general market knowledge only. There are no authoritative sources for such information nationally or internationally.

Table 3. Summary of QC procedures for a CCL or SBL

QC Category	Required Activity	Desired Result
Raw materials	Set Atterberg limits and PI	PI > 10%
	Establish maximum particle size	25–50 mm
	Establish maximum gravel content	<20%
	Establish minimum fines content	>30%
Equipment	Ensure adequate compactor weight	>15–20,000 kg
	Ensure adequate footed roller	>20 cm
Compaction	Establish minimum number of passes	>6
Liner lifts	Establish maximum loose lift thickness	25 cm
	Establish maximum compacted lift thickness	15 cm
	Ensure previous lift surface is scarified	Yes
	Measure in-place density	Within acceptable zone
	Measure in-place moisture	Within acceptable zone
	Measure lab permeability	Below minimum requirement
	Measure in situ permeability	Below minimum requirement
	Protect against desiccation cracks	Yes

GEOSYNTHETIC CLAY LINERS

GCLs represent an interesting subset of clay barriers. Part geosynthetic material and part bentonite clay, these unique hybrids are growing in popularity as partial or complete substitutions for CCLs because of their attractive price, ease of installation, and high performance under demanding site conditions.

GCL Types and Production Methods

GCLs consist of a layer of bentonite clay bonded to one or more geosynthetic materials such as geotextiles or geomembranes. GCLs are separated in to two broad classes based on their internal shear-strength properties:

- **Unreinforced**—These GCLs contain bentonite clay, which, when hydrated, offers only as much shear strength as the clay itself. Examples of unreinforced GCLs include Claymax 200R (CETCO, Arlington Heights, Illinois) and Gundseal (GSE, Houston, Texas). It should be noted that these products differ significantly. Claymax is made with a layer of bentonite laminated between two encapsulating geotextiles. Gundseal consists of a layer of bentonite adhered to a geomembrane. Unreinforced GCLs are used in applications where significant shear forces are not expected. Gundseal is occasionally used on slopes, however, if the bentonite layer is permanently protected from hydration.
- **Reinforced**—These GCLs consist of bentonite clay sandwiched between two geotextiles that are needle-punched or stitched together to reinforce the bentonite layer and to give it additional shear strength. Reinforced GCLs are used in applications where the liner system must be able to withstand shear loads. Examples of reinforced GCLs include Bentomat (CETCO); Bentofix (N AUE GmbH & Co.,

Lübbecke, Germany); and NaBento (HUESKER Synthetic GmbH, Gescher, Germany).

Designing with GCLs

GCLs are intended to replace CCLs. Many GCL design issues involve the comparison of GCL performance to that of CCLs in various situations. These equivalency issues can be categorized as hydraulic, geotechnical (slope stability), and chemical (compatibility with liquid contaminants).

Hydraulic Performance

The hydraulic performance requirements for CCLs are clearly regulated in terms of liner thickness and permeability. From these parameters, a designer can use Darcy's law to determine whether the steady-state flow rate from a GCL can be considered equivalent to that of a CCL under the same confining pressure and head pressure conditions. To perform this analysis, it is necessary to understand that GCL permeability varies considerably with confining stress (Figure 9), and so it is necessary to ensure that relevant confining stress conditions are used in the calculation. GCL manufacturers can also provide flux data to allow a direct comparison of GCLs and CCLs under similar conditions.

Based on several years of test data and successful field usage, GCLs are now generally considered to be fundamentally equal, if not superior to, CCLs in terms of baseline hydraulic performance, most notably for landfill bottom liner applications where high confining stresses result in low permeability and flux values. Data collected from landfills in the United States (Bonaparte, Daniel, and Koerner 2002) indicate that liner systems containing a GCL leak less than those containing a CCL (Figure 10). These data do not independently compare GCLs and CCLs because the liner systems also contain a geomembrane component. Nevertheless, it is clear that a GCL-based liner system outperforms other liner systems at each life cycle stage of the landfill.

Seam Flow

In any geosynthetic liner system, the potential for a leakage problem is greatest at the longitudinal and lateral seams where adjacent liner panels are connected. With GCLs, there is no mechanical attachment of the panels; they are merely overlapped. Some GCLs require additional granular bentonite along the overlap to ensure that self-seaming occurs. Properly installed, GCLs have been proven to be self-seaming such that the hydraulic performance of the seam is almost the same as unseamed material (Estornell and Daniel 1992). Achieving this result requires some confining pressure, approximately 7 kPa. Cover soil layers typically provide this confinement, with the additional benefit of physical protection of the liner system from equipment, animals, and erosion.

Slope Stability

GCLs demand special attention with respect to slope stability. The designer must be aware of the internal strength of the GCL and the strength of its two external interfaces. Project-specific direct shear testing is needed to understand these properties. When project-specific materials are evaluated at a competent geotechnical laboratory, the resulting data can be entered into a mathematical model to assess the stability of the planned design.

Many useful mathematical stability modeling techniques have been developed (Giroud and Beech 1989; Wilson-Fahmy and Koerner 1993; and Soong and Koerner 1996, to name only a few) that expertly address this paramount design concern. Using one of these models, in combination with previous project experience,

large-scale laboratory shear test data, and conservative engineering assumptions, it is possible to design a stable slope even when multiple soil and geosynthetic layers are placed adjacent to one another.

The designer must also assess global slope stability, which is related to the stability of the soil beneath the liner. Global stability considerations can be evaluated using several textbook methods. Koerner (1994) gives a good summary of these considerations.

Interface Shear Strength. A thorough stability analysis requires evaluating every interface in the liner system. Ideally, each interface should be capable of generating enough friction to transfer the driving force into the subgrade. The amount of friction for a given combination of soil and/or geosynthetic layers can be expressed as an angle when the shear strength is measured at several normal stresses. For example, the interface friction provided by a soil cover layer can be tested by measuring the shear strength at normal stresses of 100, 300, and 500 psf (5, 14, and 24 kPa). The angle described by the line connecting these shear values is the friction

Figure 11. Sample slope stability diagram for a soil layer resting on a GCL, which in turn rests on a compacted clay liner

angle between the top of the liner and the cover soil. In a simple sliding block analysis, the slope is stable if the friction angle is greater than the slope angle (Figure 11).

Internal Shear Strength. The first bentonite liners on the market in the mid-1980s were unreinforced, meaning that the internal shear strength of the GCL was no greater than the low shear strength of the hydrated bentonite layer (around 8°). The resulting design process was, therefore, relatively straightforward, although quite limiting because of bentonite's low shear strength. When needlepunched products such as Bentomat were introduced in the early 1990s, peak internal shear strength properties increased significantly. These products can safely be placed on much steeper slopes.

Internal shear strength must be demonstrated both in the short term and the long term, and ideally for the life of the lined facility. Laboratory research (Trauger, Swan, and Yuan 1996) indicates that needlepunch-reinforced GCLs can sustain long-term shear loads. Field-scale testing (Koerner 1996) and actual project experience have yielded similar conclusions relating to the high internal shear strength of GCLs in commonly encountered liner configurations. From the data and experience gained to date, it is reasonable to assume that GCLs will maintain significant internal strength in the long term.

Chemical Compatibility

Any liner must have the ability to resist chemical attack when used in containment applications where contaminants may be present. Although chemical compatibility is actually a subtopic of hydraulic performance, this issue is worthy of a separate discussion.

Sodium bentonite is an effective barrier primarily because it can absorb large quantities of water (i.e., swell). When the bentonite component of the liner hydrates, it becomes a dense, uniform layer with exceptionally low permeability. Water absorption occurs primarily because of the presence of sodium ions situated in the interlayer region between clay platelets (Figure 12).

Contaminant Effects. Sodium bentonite that is hydrated and permeated with relatively clean water will be an effective barrier indefinitely. The interlayer sodium ions, however, can be

exchanged with other cations that may be present in the water during the hydration or permeation process. This type of exchange reaction reduces the amount of water that can be held in the interlayer, resulting in decreased swell. Anions will also reduce swell. The loss of swell usually causes increased porosity and decreased performance as a hydraulic barrier; this is the primary mechanism for the chemical contamination of bentonite. Other chemicals such as organic molecules are far less likely to affect bentonite and are seldom encountered in concentrations needed to affect its performance. Table 4 lists potential bentonite contaminants that are commonly found in liquids requiring containment.

Experience has shown that calcium is the most common source of compatibility problems for bentonite-based liners. Other cations (magnesium, ammonium, potassium) can also contribute to compatibility problems, but they generally are not as prevalent or as concentrated as calcium (Altherr et al. 1985). Such cations may already be present in the water to be contained or may leach into the water from cover soils on the liner.

It is not possible to specify the maximum concentration at which a certain chemical becomes a compatibility problem because of the many variables involved in assessing performance. These variables include exposure time, confining stress, hydraulic pressure, hydration liquid, temperature, and chemical interactions between different contaminants. In lieu of blanket recommendations, routine compatibility tests (ASTM D6141 and D6766) should be performed to determine if the chemical or leachate can affect the liner. The liner may also be sensitive to the chemical composition of soil placed over it, such that limestone and other calcium-rich cover soils should be avoided.

Construction

A primary advantage of GCLs over CCLs is their relative ease of construction. Supplied in rolls, GCLs are installed by unrolling the material along the intended path of deployment (Figure 13). A spreader bar and core pipe suspend the roll freely from the moving equipment. Installation rates of 1 ha/day (2.5 acres/day) are not uncommon on large projects, which is a significantly faster deployment rate than for CCLs. Deployment should begin only when the subgrade surface has been made smooth, stable, and free of protrusions.

At the top of a slope, the end of the GCL roll is typically placed in an anchor trench to prevent downslope movement or to promote slope stability (Figure 14). The GCL can be cut with a utility knife to the necessary length and can be installed around foundations and appurtenances by cutting and sealing with dry bentonite or a bentonite paste (Figure 15). GCL manufacturers provide detailed installation guidelines covering other common installation situations such as perimeter wall connections, repairs, pipe penetrations, and corners.

One of the most important steps in the GCL installation process is covering. If covered with another geosynthetic layer (such as a geomembrane), the GCL is not as susceptible to damage by subsequent site activities. If the GCL is covered with soil, however, as is common in landfill cap applications, the GCL can be damaged. Designers should specify the minimum soil thickness that should be maintained between the GCL and covering equipment, and covering activities should be carefully monitored to ensure that the equipment does not come in direct contact with the GCL.

Quality Control

GCLs are factory-made liners and many undergo quality tests in accordance with ASTM D5889. The raw materials (bentonite clay, geotextiles, and geomembranes) undergo testing, as does the

finished GCL product. The engineer receives QC information upon delivery to ensure that quality criteria have been achieved. The factory-oriented QC process for GCLs means that there is little field QC required, which results in time and cost advantages over CCLs.

Engineers often require additional quality data such as permeability or direct shear test data before granting final approval of the GCL materials. The scope and frequency of these tests are quite dependent on the nature of the project. In general, GCLs exhibit consistent hydraulic and mechanical properties, tending to reduce the need for frequent (and costly) tests.

Economics and Market Trends

The GCL market is fairly stable in North America but is rapidly evolving in other parts of the world. The two major GCL manufacturers in North America share a market estimated to be 15 million sq m in 2004. Europe, with a 2004 estimated market of 12 million sq m, has approximately six GCL manufacturers, creating a more fragmented and regionalized marketplace that caters to the unique regulatory, cultural, and economic status of European countries.

Asia has approximately four credible GCL producers, with up to 15 other companies (many in China) claiming to provide GCLs. The largest Asian GCL market is China, whose rapidly expanding economy requires secure waste containment facilities. Hong Kong, Korea, and Japan have used GCLs for a longer period of time, since approximately 1993, but they are not perceived as growth markets. The total Asian market is approximately 3 million sq m.

GCL pricing has decreased dramatically since its introduction in the early 1990s. North American unit pricing at that time was approximately \$5.50/sq m but has since dropped to an average of \$3.00/sq m for standard products (on a medium-sized project of 10,000 sq m). The price decrease represents the evolution of GCL technology from low-volume specialty product to high-volume commodity product. Pricing levels in North America have been relatively stable since 1999, with occasional price increases offsetting increased raw materials costs. In Europe and Asia, pricing over the past 5 years has fallen more quickly, although these markets are also showing signs of stabilization. Another factor affecting prices has been consolidation within the geosynthetics industry, where various mergers and acquisitions are creating a stabilizing force in the GCL market.

GCLs are heavy, and freight costs are often significant. In North America, freight costs range from \$0.10/sq m to \$0.70/sq m,

with an average of \$0.40/sq m. Exporting GCLs from Europe or North America adds ocean freight costs and increases the typical freight charge to \$0.60–\$1.00/sq m.

A nominal estimate of the installation cost of GCLs in North America is \$1.50/sq m. This cost includes only the materials handling and deployment processes and does not include appurtenant activities such as subgrade preparation or covering. In consideration of labor wages worldwide, deployment costs in Asia are expected to be somewhat lower than this amount, whereas in Europe (especially Western Europe) deployment costs would be higher. In total, then, the installed cost of a GCL in North America can be reasonably estimated as \$4.90/sq m (\$3.00 + \$0.40 + \$1.50).

CUTOFF WALLS

Cutoff walls are a unique category of clay barriers. In consideration of the vast amount of horizontal clay barriers used worldwide for water and waste containment, the usage of cutoff walls is small and the discussion contained herein is limited. Detailed design and construction methods are available in works by Spooner et al. (1985), Xanthakos (1985), and Noyes (1975). In addition, two ASTM publications (Alther et al. 1985; Millet, Perez, and Davidson 1992) also offer relevant information from previous technical symposia on slurry walls. Cutoff walls still represent an important technology, however, for controlling groundwater flow and for mitigating the damage created by ineffective horizontal barriers built in decades past.

Design

Cutoff wall applications involve building a subsurface vertical barrier to control groundwater or contaminant flow. Therefore, the first step in the design of a subsurface barrier is to evaluate the site conditions and overall feasibility (Spooner et al. 1985). In certain cases, limited access because of existing infrastructure may not allow the area of concern to be encircled to the extent necessary to control groundwater movement. Additionally, the depth to groundwater must be evaluated to ensure that it is close enough to grade to allow trenching. Most cutoff walls are not feasible or cost-effective if the depth is greater than 30 m, although successful cutoff walls have been installed as deep as 125 m. Finally, the geology of the site must be examined to determine whether trenching is possible. Sites with shallow bedrock are seldom acceptable for cutoff wall techniques and sites without an accessible aquiclude may not be feasible for cutoff wall construction.

Assuming that there are no insurmountable site and feasibility restrictions, the next phase of design involves selecting the type of wall to install. There are many types of cutoff walls, each with their own set of advantages and limitations. Walls containing clay as the principal hydraulic barrier are SB walls, CB walls, and SCB walls. The designer selects the appropriate wall type based on the nature of the subsoils, the hydraulic performance requirements for the cutoff wall, chemical compatibility issues (Day 1994), structural considerations, and cost. With information pertaining to site constraints and performance requirements, it is possible to select a wall type most suitable for the project. Table 5 lists some of the major points of comparison between SB and CB walls. SCB walls would fall in the middle of these ranges.

The next step in the design is to create a specification for the installing contractor. The specification should include all relevant performance properties of the construction materials and the finished wall, including final permeability, compressive strength, and thickness. Darcy's law can be used to determine the wall thickness required for adequate containment at a certain *in situ* permeability. It is also possible to provide a performance specification in which

Table 5. General comparison between SB and CB cutoff walls

Design Parameter	SB	CB
Permeability	Lower (10^{-8} – 10^{-9} m/sec)	Higher (10^{-7} – 10^{-8} m/sec)
Strength	Low	Higher
Constructability	Harder	Easier
Chemical compatibility	Varies	Varies
Cost	Lower	Higher

methods and materials are left to the discretion of the contractor (Spooner et al. 1985).

Construction

Cutoff wall construction typically involves four concurrent steps: *slurry mixing*, *trench excavation*, *backfill mixing*, and *backfill placement*. Slurry mixing involves using an aqueous bentonite mixture that is pumped into the trench to prevent collapse during excavation. With a density greater than that of water, the slurry displaces groundwater, coats the interior of the trench walls, and stabilizes potentially unconsolidated soils that may be prone to collapsing the trench. The slurry is mixed in dedicated tanks equipped with high-shear impellers for completely dispersing the bentonite. The concentration of the bentonite slurry is usually in the range of 4%–7%, although it is more typical to specify the viscosity of the slurry rather than its bentonite concentration. Throughout the slurry mixing and trenching process, the quality of the fluid must be continually checked to ensure it does not become contaminated with soil particles.

Trench excavation is accomplished with a backhoe or, for deeper walls, a cable-suspended clamshell. Many purpose-built attachments and enhancements to this equipment have been developed to facilitate efficient excavation in wide-ranging subsoil conditions such as sands, stiff clays, and rock (Millet, Perez, and Davidson 1992). The most critical aspect of the excavation process is preventing trench collapse. This requires a well-developed plan for integrating the activities of the slurry and the excavation equipment. Another important excavation parameter is the verticality (plumbness) of the trench; it is always to be desired, especially if the finished wall must meet certain strength requirements.

Backfill mixing refers to the ingredients constituting the barrier component of the trench. These ingredients will consist of native soil, bentonite, cement, or some combination of the three. Attapulgit is sometimes used as an alternative to bentonite. The primary objective in mixing the backfill is to achieve uniformity of the mixture to prevent the development of preferential flow zones. It is also necessary to ensure that the mixture is sufficiently wet to flow evenly into the trench. To accomplish these objectives, the designer may specify particle-size requirements for the bentonite and the soil backfill. In most cases, the bentonite content of the backfill mixture will be approximately 2%–4% by weight and the water content will be 25%–35% (Millet, Perez, and Davidson 1992).

Backfill placement is accomplished either by injecting the mixture through a tremie pipe to the bottom of the trench or by pushing with a bulldozer and allowing it to fall by gravity along a sloped surface at the end of the excavation. Backfill is placed in this manner until it daylight at the top of the trench, by which time the bentonite slurry has been displaced in the area by (ideally) a contiguous layer of low-permeability, reasonably well consolidated backfill. If a CB wall is being built, there is no backfilling process; the CB slurry used to stabilize the trench is simply allowed to harden in place.

The cost of an SB or CB wall is, as would be expected, highly variable, but in soft or medium-soft soils, \$540–\$750/sq m is expected (EPA 1994). CB walls would trend to the higher end of this range.

Quality Control

A comprehensive QC program is required for the cutoff wall to function as designed. Quality testing is performed throughout the construction process to ensure adequate trench depth, excavation into the aquiclude, trench alignment, and trench width (wall thickness). The bentonite or CB slurry should be checked for viscosity, pH, and sand content. The CB or SB backfill should be regularly checked for slump, density, fines content, and hydraulic conductivity. Samples of the backfill should be taken both at the source and in situ. The slope of the backfill trench must also be monitored to ensure that the backfill is deposited properly (Khoury, Fayad, and Ladd 1992).

PERFORMANCE OF CLAY BARRIERS

There is little doubt that early attempts at constructing horizontal and vertical clay barriers were not as successful as they are today. Considerable advances in geotechnical engineering, expanded academic and field research on clay barriers, the development of better test equipment and methods, and tremendous improvements in construction equipment and QC practices have helped greatly improve the success rate of modern clay barriers.

Field Monitoring Data

Indirect evidence of the failure of some clay barriers is present in the number of old landfills that have caused serious environmental contamination. Hundreds of Superfund sites are landfills, a reminder that clay barrier technology was not effective in the past. To be fair, most of the Superfund landfill sites never contained a liner of any type, but many contain a clay liner that was unable to provide suitable containment.

As the incidents of contamination increased, and as general public and scientific awareness of environmental problems also increased, federal research monies were made available to study clay barriers more intently. Research performed by Haxo et al. (1984) showed that chemicals could degrade clays. Elsbury et al. (1990) and Rogowski (1990) showed that there was a dramatic difference between laboratory permeability and actual field performance, where “actual” field permeabilities were several orders of magnitude greater than the designed design value. Additional research (Bo ward and Vallejo 1996; Omidi, Thomas, and Brown 1996; Albrecht and Benson 2001; Chapuis 2002) has shown how desiccation cracks can increase the permeability of clay barriers. And several researchers have documented that freeze/thaw cycling can also cause increased CCL permeability by up to two orders of magnitude (Chamberlain, Iskander, and Hunsiker 1990; LaPlante and Zimmie 1992; Othman and Benson 1992).

As research accumulated demonstrating that clay liners were often underperforming in the field relative to laboratory tests, a different understanding of clay liners emerged. They were not monolithic barriers with a fixed permeability in which flow strictly obeyed Darcy’s law. Instead, flow through a clay liner was governed by the presence of large-scale defects such as cracks, clods, rocks, and poor interlift bonds. A “short circuit” effect (Figure 16) caused leakage to propagate around and through these defects, resulting in much higher leakage rates than small-scale laboratory permeability tests would reveal.

The sealed double-ring infiltrometer (SDRI) shown in Figure 17 is an important tool for measuring field performance of CCLs

Adapted from Daniel and Benson 1991.

Figure 16. CCL and SBL leakage pathways may result in an actual flow rate far higher than that allowable

Adapted from ASTM D5093.

Figure 17. An SDRI (shown in cross section) is used to measure the in situ permeability of a clay liner

and SBLs. It offers two advantages over conventional laboratory permeameters. First, the SDRI is installed in an in situ liner so there are no sampling-induced errors that often occur when small-scale permeability samples are extracted. Second, the SDRI is a large-diameter device (>1 m) and can capture macroscale defects such as cracks and interlift flow pathways that might otherwise escape detection. SDRI data, if properly obtained, give a good indication of the field permeability of a clay liner. The relative time and expense of this test, however, make it impractical to perform with the same frequency as small-scale permeability tests.

In the late 1980s and early 1990s, more effort was applied to develop enhanced standards for clay materials screening and to improve the methods of clay barrier construction. With tightened materials and construction controls in place, it is possible to construct clay liners that meet or exceed the required performance criteria. Bonaparte, Daniel, and Koerner (2002) compiled a database of the field performance (mostly SDRI data) of 89 CCLs and found that 75% of the in situ permeability test results were less than 1×10^{-9} m/sec. Of the 22 test pads that did not meet this value, 18 of them measured less than 3×10^{-9} m/sec.

Evaluation of field QC data revealed that the dominant cause for the “failing” permeability test results in these 22 sites was that the soils were compacted at insufficient moisture content (Figure 18). Best results are achieved when the moisture content during compaction is as wet of optimum as feasible. There is a trade-off

Source: Bonaparte, Daniel, and Koerner 2002.

Figure 18. Relationship between CCL permeability and compaction moisture content

between shear strength and permeability, but the data suggest strongly that the soil should be as wet of optimum as possible to maximize the potential for achieving low permeability.

GCLs as a Replacement for CCLs

The development and commercialization of GCL technology have been largely coincident with the development of CCL performance data. As it became apparent that CCLs needed far more engineering analyses, installation expertise, and CQC to perform successfully, GCLs were naturally viewed as an easy solution to the problems of CCLs. GCLs were widely embraced by engineers in the early 1990s (in North America, and somewhat later in other parts of the world), although regulatory acceptance was slow because of the institutional inertia of CCLs and the fundamental thickness difference between the two technologies (there is a perceived risk in replacing a thick liner with a thin one, regardless of the equivalency argument).

GCL manufacturers were quick to identify the technical and practical advantages of their products in light of the growing realization that CCLs often underperform. In time, GCL use in both waste containment and other applications increased to the extent that some generalizations about their field performance could be made in comparison to CCLs. In this regard, many of the performance advantages claimed by GCL proponents were verified (see Hydraulic Performance section), although at the same time, significant engineering limitations of GCLs were also being discovered. These limitations relate mostly to slope stability and chemical compatibility. With a large database of direct shear test results available (Chiu 2002; McCartney, Zornberg, and Swan 2002), the engineering community has a much better understanding of how GCLs perform in many different sloped applications. Additional research (Ruhl and Daniel 1997; Egloffstein 2000; Jo et al. 2001) has set the practical parameters for determining the potential effects of chemical contaminants. There is now enough field experience and laboratory data on GCLs to allow designers and regulators to understand and predict the performance of a GCL in a specific application.

State of Practice of Clay Barriers

Clay barriers have improved considerably since they were first used in waste containment applications in the 1970s. With a better understanding of the engineering properties of CCLs and GCLs and with the advent of rigorous materials and CQC programs, the performance of clay barriers has improved appreciably. These performance improvements have a direct beneficial effect on the protection of human health and the environment.

Although the quality of clay barriers has increased, it is also necessary to briefly discuss the development of geomembrane technology. Maximum containment is achieved only when geomembranes and clay barriers are used together. A clay barrier, regardless of how well it is constructed, is always permeable. A geomembrane, however, is fundamentally impermeable (to liquids) and offers close to 100 % containment. But geomembranes are prone to leakage caused by puncture or improperly welded field seams. With a clay layer present beneath the geomembrane, the amount of leakage is greatly reduced. Indeed, a synergistic effect between the geomembrane and the clay barrier (GCL or CCL) has been modeled by Bonaparte, Giroud, and Gross (1989) and Giroud (1997). These researchers have determined that if the geomembrane and clay barrier are in "intimate hydraulic contact" with one another, the resulting leakage through a geomembrane defect is almost inconsequentialy small.

Therefore, the current state of the practice in modern liner design is to include both a geomembrane and a clay barrier, a system that has proven to give the highest level of containment achievable at reasonable cost. Even better performance is possible if the liner system is subjected to a leak location survey before being put into service. Such surveys can identify the location of geomembrane and GCL defects that might otherwise have contributed to increased flow. The final result of this evolutionary process of liner design and construction is a nearly leak-free liner system. Although it is never possible to guarantee "perfect" leak-free performance, it is possible to approach it.

This does not mean that liner system design practice is at a standstill. The previously described performance improvements apply only to advective flow. As progress is made in eliminating advective flow, diffusive flow—especially of organic contaminants—will begin to challenge the next generation of designers and researchers. Thick clay barriers may once again play an important role in the development of strategies to minimize diffusive flow.

Flue Gas Desulfurization

David C. Hoffman and Robert C. Freas

Beginning in the 1970s, people throughout the world, especially in Western Europe, Japan, and the United States, have taken more interest in the environment, the sources and causes of pollution, and pollution abatement. In the United States, air quality continues to be an area of primary emphasis. In 1970, for instance, the U.S. Congress passed the Clean Air Act and subsequently revised and strengthened it in 1977 with the issuance of the New Source Performance Standards (effective August 7, 1980). The act was toughened further with the passage of the 1990 Clean Air Act Amendments (CAAA) that created the current Acid Rain Program to address sulfur dioxide (SO_2) and oxides of nitrogen (NO_x) emissions. Additionally, this update included a list of 189 hazardous air pollutants (HAPs) that continues to be evaluated and refined. Most significantly, the 1990 CAAA established a phased program for implementation via a novel cap-and-trade method for attaining allowable emissions.

Because this chapter focuses on SO_2 removal, it should be pointed out that an unwanted by-product of certain NO_x removal technologies has emerged—an increase in sulfur trioxide (SO_3) emissions. The major source of the increased SO_3 , a significantly more toxic and visible substance than SO_2 , is primarily from selective catalytic reduction (SCR) systems employing vanadium-based catalysts.

By far the largest single source of emissions addressed in the Clean Air Act from the 1970s through the 1990 CAAA was from large coal-based electric power generating stations. Consequently, a substantial portion of flue gas desulfurization (FGD) research, development, and equipment installation has been geared to this large utility sector. Several competing FGD technologies were touted during the 1970s, employing various equipment configurations and different reagents to react with and reduce the gaseous SO_2 emissions. At the beginning of the 1990 CAAA's Phase I, the most viable FGD processes were generally equipment configurations employing either limestone or lime as the reagent, and they have continued to be the reagents of choice into the 21st century.

In 2004, a second area of emphasis for FGD has been coal-based industrial boilers. Although individually they are much smaller than any electric utility generating station, they represent a significant source of sulfur emissions. Because of the size of industrial boilers and their location within industrial, commercial, and educational complexes, however, the well-accepted wet scrubber technology employed by electric utilities is not universally appropriate for these applications. Therefore, other types of FGD

equipment and reagents have been developed that meet emission-reduction requirements and are cost-effective for the user.

One particular type of process employed is fluidized bed combustion (FBC) technology. Briefly, FBC suspends the fuel and ground limestone with combustion air, and the ground limestone is the SO_2 removal reagent via in situ calcination to calcium oxide (lime). Since the installation of the first full-scale test unit at Georgetown University (Washington, D.C.) in 1979, several equipment vendors have come forward with an increasing array of more sophisticated FBC units. Currently, FBC technology has reached a technical and economic plateau, in the 250- to 300-MW range, and some are in operation across the United States.

Currently, this large pool of industrial boilers is being analyzed, and emission regulations are being proposed to address the interstate transport of SO_2 and other air pollutants, such as fine particulates and ozone. The most current U.S. Environmental Protection Agency (EPA) proposal on the interstate transport of SO_2 was published in the *Federal Register* on January 30, 2004. This initial proposal is subject to public comment, and, if it stays intact, will affect 29 eastern states and the District of Columbia. SO_2 emissions within this region would drop to 3.6 million st in 2010 (approximately 40% of 2002 levels) and another 2 million st by 2015 (approximately 70% of 2002 levels). NO_x regional emissions will be cut by 1.5 million st in 2010 and another 1.8 million st in 2015—a reduction of approximately 65% from 2002 baseline levels. Quite significantly, emissions will be capped at these levels, with any increases handled by “trading.” The 1990 CAAA, then, created an “ SO_2 emissions allowance per ton of SO_2 emitted” that is equivalent to a corporate stock certificate, and these “allowances” are also publicly traded.

Mercury is now being seriously addressed as a result of the 1990 CAAA's requirement for the EPA to study public health effects of airborne toxic emissions from utilities burning fossil fuels. Again, the utility sector is the largest source of mercury emissions. On December 15, 2003, the EPA proposed two alternatives: (1) installing “maximum achievable control technologies” (MACT) with a planned mercury reduction of 14 st, or 2.9%, by the end of 2007, or (2) establishing “standards of performance” limiting emissions from new and existing utilities in two phases. The first phase of the latter alternative would take advantage of “co-benefit” controls reducing mercury emission via SO_2 and NO_x emissions by 2010 and full implementation by 2018 with reductions amounting to 33 st, or 69%. Mercury reductions are a hotly contested

technology—scientifically as well as economically—and on March 15, 2005, the EPA issued the first rules on mercury emissions.

1990 CLEAN AIR ACT AMENDMENTS

As passed, the 1990 CAAA empowered the EPA with extensive regulatory powers. The amendments are composed of 11 parts, or titles, that impact most major industries in the United States, including the mining industry. Title IV, Acid Rain Control, however, has the greatest impact on FGD requirements for utilities and other industrial coal-based sources of sulfur emissions. A much overlooked section of the CAAA, Title III, Hazardous Air Pollutants, addresses 189 airborne toxic substances that are required by law to be controlled by a MACT. With a combination of theoretical research and, most importantly, actual operating technologies, emission reductions of each airborne toxin will be mandated and implemented using MACT guidelines. This is a new approach using the best operating systems to establish the baseline emission regulation. Thus far into the 21st century, these HAP controls have proved to be the real challenge.

Title IV was implemented in two phases. Phase I ran from 1995 to 2000 and was applied primarily to the largest coal-based sources from 1995 to 1999. In fact, 110 electric generating stations in 22 states were listed (*Congressional Quarterly* 1990; Bureau of National Affairs 1991). The basic sulfur emission allowance is calculated at a rate of 1.1 kg (2.5 lb) of SO₂ per million Btu of heat input multiplied by the amount of fuel burned in that particular unit. During this Phase I period, about 89,000 MW of generating capacity were equipped with FGD systems.

Phase II, which began in 2000, further tightens the restrictions of Phase I and also triggers NO_x emission controls for these units. The Phase II calculation is based on 0.5 kg (1.2 lb) of SO₂ emissions per million Btu and also includes restrictions on NO_x emissions, which have been clearly identified with the decline in air quality and are part of the Acid Rain Program. Further NO_x emission reductions have been implemented at state levels to address regional air pollution concerns caused by haze and smog. Thus, the federal government prompted the installation of several types of NO_x reduction systems and processes on major power plants through state implementation plans. The timetable for full compliance is now clearer as more units become operational, and a May 1, 2007, deadline seems more achievable.

ACID RAIN CONTROL RESULTS

At the end of 2002, the 1990 CAAA achieved the following results:

- Electric generating sources (3,208 units) reduced annual SO₂ emissions in 2002 by 41% from 1980 levels, or about 7.1 million st. (Banked SO₂ allowances have steadily decreased from 2000 to 2002.)
- Total NO_x reductions in the Acid Rain Program achieved a goal of 2 million st below projected emissions without Title IV enforcement in 2000. Actual results of 3 million st below projections were achieved by adding state controls, primarily in the Northeast.

Although results exceeded most expectations, there is continuing pressure to reduce these pollutants further and to continue to protect public health and welfare for future generations.

FLUE GAS DESULFURIZATION TECHNOLOGIES

Overview

Several technologies are available to both utility and industrial boiler operations for reducing SO₂ emissions. These include wet lime or limestone scrubbing, semidry scrubbing, dry scrubbing, and

Table 1. Existing FGD systems

Reagent Type	Megawatts Scrubbed	Percentage
Lime-Based		
Magnesium-enhanced	14,100	14.4
Semidry	9,200	9.4
Wet lime	5,100	5.2
Lime-F/A*	4,300	4.4
Other	200	0.2
Total Lime-Based	32,900	33.6
Wet Limestone	55,800	57.2
Other	8,900	9.1
Totals	97,600	100.0

* F/A = fly ash.

FBC technology, as well as several less well-known and essentially unproven systems. The selection of a particular process is typically an economic one, but other considerations are the sulfur and Btu contents of the coal, the cost of SO₂ sorbent, the disposal of solid waste generated by sulfur removal, and local socioeconomic factors. In addition, alternatives such as the implementation of coal-cleaning or gasification technologies, solvent-refined coals, and firing with coal-water mixtures or other coal blends also impact the selection of a sulfur-removal system. The Electric Power Research Institute has sponsored research on all the primary FGD methodologies as well as investigations of the availability and effectiveness of a variety of sorbents (EPRI 1991).

At the end of 2002, the total U.S. electrical generating industry (utilities and nonutilities) consisted of the following:

- Net summertime generating capacity of approximately 905,000 MW, including
 - Electric utilities' capacity of approximately 561,000 MW, or about 62% of U.S. generation
- Net summertime coal-based generating capacity of approximately 315,000 MW, or about 35% of U.S. generation, including
 - Electric utilities' capacity of approximately 244,000 MW, or about 77% of generation and about 27% of total U.S. generating capacity
 - 100,000 MW of scrubbed coal-based units, or 32% of U.S. coal-based capacity and 11% of total U.S. generating capacity

In summary, the United States has come a long way since 1970 in improving the air quality with respect to SO₂ removal, but 67% of coal-based capacity still needs attention to reduce SO₂ emissions.

Wet Scrubbing

About 90% (based on megawatts scrubbed) of the existing electric utility generating units with commercial FGD systems employ lime-limestone processes based on wet calcium. Table 1 breaks these FGD systems down further.

Although the wet lime and limestone reagents are uniquely different, the basic process chemistry is similar. The details for a wet lime or limestone system are fairly complex and include both the liquid phase chemistry of SO₂ absorption, the liquid-solid chemistry of lime-limestone dissolution, and the liquid phase precipitation of calcium sulfite-sulfate salts. Calcium reagent materials, either lime or limestone, provide alkalinity for SO₂ removal in the wet scrubber. This generates sulfite and sulfate salts as calcium-based by-products

from the removal of the SO_2 from the flue gas stream. These by-products may be in slurry form or a high solids filter cake, but in either case they require an environmentally safe disposal or reuse. Because this chapter is not intended as an in-depth discussion on scrubber systems, the reader is referred to a report written by Srivastava (2000).

Since the mid-1990s, the preferred method of disposal for scrubber by-products has been the conversion-oxidation of these salts into calcium sulfate (or gypsum) for, primarily, wallboard construction. This synthetic gypsum is technically competitive with natural products but is economically dependent on the location of the FGD source materials and major construction markets.

Another factor in deciding between wet lime and wet limestone systems is the solubility and dissolution rates of these calcium-based reagent materials and how they will affect the total alkalinity per gallon of reagent slurry recirculated within the scrubber. In very general terms, wet lime systems require less hardware and less tonnage of calcium-based reagents than a wet limestone system to remove sulfur from flue gas. Today, it is not uncommon to achieve SO_2 removal efficiencies in ranges of 98%+ from either lime- or limestone-based FGD systems. These wet systems usually are applied to coal-fired flue gases that are in excess of 1.5% sulfur. Both reagents (lime and limestone) require buffering agents. When using lime, magnesium oxide is added to quicklime, or magnesium-dolomitic lime is used. In limestone systems, the addition of weak organic acids helps to obtain these high SO_2 removal efficiencies on a consistent basis. Such buffers as adipic acid, dibasic acid (DBA, the most common), and formic acid can enhance limestone removal and utilization, especially to achieve continuous 95%+ SO_2 removal efficiency.

In deciding between lime or limestone reagents, the following are major evaluation parameters:

- Availability and cost of required land area
- Capital installation costs
- Reagent costs (including delivery) and slurring costs:
 - Lime: slaking systems
 - Limestone: fine grinding systems with >90%+ passing 44 μm
- Reliability of reagent supplier(s)
- Technical support from reagent suppliers
- Parasitic electrical demand for complete FGD system evaluated at current electrical market replacement costs
- Ability to remove additional pollutants (e.g., SO_3 and mercury currently addressed by MACT)
- Cost of disposal or resale of by-products (primarily gypsum and fly ash)
- Water treatment requirements for effluent water discharges in terms of quality and volume

The most common equipment FGD design is an open spray tower that can handle the flue gases from 800 to 900 MW per tower. Reagent utilization varies and is generally in the range of 1.02 to 1.10 moles of reagent applied per mole of SO_2 removed.

Semidry Scrubbing

Semidry scrubbing involves reacting a sulfur-containing flue gas with an alkaline reagent slurry resulting in a dry by-product being generated and captured for disposal or reuse. These systems use spray atomizers or dual fluid injection systems prior to baghouse filters or electrostatic precipitators to remove reaction by-products. Today, the most common atomizer is the rotary disc type that spins at several thousand revolutions per minute, producing a fine mist that contains the slurried reagent. These units have been used successfully in industrial boilers, municipal waste incinerators, and utility plants.

Limestone cannot be used in these systems because they rely on the SO_2 and lime reaction plus the evaporation of the slurry water to occur in a matter of seconds. The preferred reagent is lime; however, some systems use sodium carbonate or bicarbonate reagents. Sodium is generally more costly than lime, and sodium-based by-products can be deleterious to the environment because of sodium's high solubility and mobility.

In a very simplified form, the spray dryer incorporates a milk-of-lime slurry, which is atomized to a fine particle size, typically 50 to 75 μm in diameter. The slurry is sprayed into the reaction chamber at a low moisture level allowing the SO_2 -CaO (calcium oxide) reaction to take place and for the slurried water to evaporate. A fabric filter or electrostatic precipitator immediately follows the reaction chamber and removes reaction by-products and coal fly-ash particulates. This design is optimized when a fabric filter is employed, as it removes an additional 25% to 35% SO_2 across the bags. As a result, sulfur is removed from the flue gas as a dry waste product. Because of the physicochemical kinetics of the SO_2 reaction, each reaction module usually is limited to about 250 to 350 MW of the flue gas volume. To achieve up to 94% SO_2 removal, the sulfur content of the coal is restricted generally to less than 1.5% sulfur.

SO_2 removal and fuel sulfur levels reduce the suitability of semidry scrubbing systems. Additionally, reagent utilization is lower than in wet, open spray towers; however, by-product reuse helps reduce the overall reagent consumption. Reagent utilizations vary and are, by convention, described as moles of lime applied per mole of inlet SO_2 . Typical utilizations range from 1.25 to 1.5 with a fabric filter and by-product reuse or recirculation.

Major advantages of semidry scrubbing over wet systems are lower capital costs per applied megawatt; small land area requirements; minimal use of water; no water treatment system needed for wastewater effluent; SO_3 removal and possible mercury removal; nearly invisible stack emission; and an immediate, dry by-product for disposal. Because of its fine powder consistency and potential market outlets, the resulting economics limit its reuse applications. Today, most of these systems are used for western low-sulfur coals. The added benefits of SO_3 removal, and possible mercury capture, however, are causing many eastern utilities to rethink its suitability. Although the semidry scrubbers do not have the complex liquid-phase chemistry of wet scrubbing, they still have process limitations. These include inlet SO_2 concentrations and temperature drops across the spray dryer (i.e., approach to saturation, composition of slaking water, and lime activity). Some lime suppliers are able to assist in fine-tuning these considerations to achieve an optimal semidry FGD operation.

Dry Scrubbing or Dry Alkali Injection

The previously discussed systems involve the use of a water-based alkaline slurry that remove SO_2 and create by-products that are handled easily for disposal or for reuse or sale. In dry scrubbing, a dry, finely divided reagent is injected directly into the boiler or flue gas ducts for gas-solid reactions. Typical reagents are hydrated lime, finely ground limestone, and powdered sodium carbonate or bicarbonate material (usually the natural products called trona and nahcolite, respectively). The first initial dry scrubbing systems incorporated lime as the sorbent, but the subsequent development of dry alkali injection technology also employed trona as a reagent. Public Service Company of Colorado announced the first commercial application of a trona-based dry injection system for a 500-MW unit that began operating in the late 1990s. As previously stated, sodium-based scrubbing causes problems for handling and disposing of by-products because of sodium's high solubility, and mobility and leachability.

With the injection of these reagent(s) into the upper regions of the boiler, flue gas temperature becomes an important reaction parameter for optimizing the sulfur reactions. Of further concern is sodium's ability to corrode steel boiler tubes. The disadvantages of lime and limestone injection into the boiler are physical fouling of the boiler tubes and low SO_2 removals. With any of these reagents, removals generally are limited to less than 40% in the boiler and from 50% to 70% in the ducts when moisture is added. Duct fouling becomes a major concern when moisture is added. Reagent utilizations are typically in the 3.0 to 7.0 mole range for the calcium-based systems (based on moles of calcium applied to inlet SO_2 moles). Overall success of dry reagent applications has been quite minimal in the United States; however, limestone and lime boiler injection has had some success in Europe where lower removals are sometimes acceptable.

In duct injection, lime has been used successfully outside the high-temperature boiler regions because of its customization with respect to surface area, internal pore volume, and particle size. As HAPs and their respective MACTs gain more attention, use of special lime hydrates that have higher surface areas and pore volumes can remove certain acid gases such as hydrochloric acid (HCl) and hydrofluoric acid (HF) plus select volatile organics. With the use of these special limes, duct injection has been successful in Europe and may be employed in the United States to address various HAPs as listed in the 1990 CAAA.

In addition to these applications, dry injection with reasonable reagent utilizations in the 1.0 to 3.0 mole range for reduced removals of SO_2 (ranging from 50% to 70%) is being discussed more openly at present. In 2004, the Institute of Clean Air Companies proposed this approach to the EPA in addressing SO_2 removals from smaller and older industrial and utility boilers not covered by the 1990 CAAA. Under certain circumstances, the introduction of lime slurry or water mist into the duct subsequent to the boiler will improve the removal or increase the reagent utilization.

SO₃ Removal

SO_3 is produced from the combustion of sulfur-bearing fuels when some SO_2 —estimated at 1% to 3%—is oxidized to SO_3 . The combustion of heavy fuel oil results in the most prolific SO_3 emissions, because the vanadium contaminant of the oil catalyzes the conversion to SO_3 . In 1980, about 10% of U.S. utility generation was from heavy fuel oil. In 1999 this generation was about 2%, and today, the percentage is most likely less. SO_3 emissions regained the spotlight with the addition of SCR systems that employ vanadium-based catalysts for NO_x control. After wet SO_2 scrubbing, stations employing SCR systems might see SO_3 emissions nearly double, in addition to emitting a very visible bluish plume from stacks. This issue came to light in 2001–2002 with problems associated with an electric power plant at Gallipolis, Ohio.

SO_3 is produced as a very tiny aerosol particle readily passing through the wet scrubber and is converted into sulfuric acid smog that can settle quickly to ground level, causing severe health issues and property damage. This also occurred at the plant at Gallipolis. The solution is to inject an alkali reagent before or immediately after the SCR system. Alkalies such as magnesium hydroxide, sodium bisulfite, and calcium hydroxide have been used with limited success. The problems associated with the use of these alkalies are

- Buildup of unused reagent and reaction by-products in the ducts
- High reagent utilizations in the range from 2.0 to 10.0; typically from 2.0 to 6.0 (moles of calcium per mole of inlet SO_3)

- Consistent SO_3 removals over the range of boiler generation loads
- The lack of demonstrated SO_3 monitoring methods and continuous emission instrumentation

The most proven reagent is sodium bisulfite, but recent advances using calcium hydroxide, dry or in slurry form, appear to be the most cost-effective method. The ultimate goal of all these approaches is

- To remove SO_3 to safe levels without any visible plume—typically less than 5 ppm
- If possible, to improve boiler efficiency by lowering the air preheater outlet temperatures below the previously limiting acid dewpoint, thus greatly improving boiler energy conversion efficiency and economics

As previously mentioned, this appears to be an “eastern problem” in the United States because of the relatively higher concentration of SCRs on high-sulfur eastern coals; smog and haze concerns in national parks and scenic areas; and the use of wet FGD systems. In the American West, semidry systems are more prevalent, but even when wet FGD systems are used, coal sulfurs are usually less than 1.5%, and population densities are less. Nevertheless, the West also has scenic areas that suffer from smog and haze (e.g., the Grand Canyon).

Other FGD Systems

External fluidized bed systems for flue gas treatment using calcium hydroxide as the fluidized medium have received more attention worldwide as larger systems come online in China. They appear to present several advantages, such as lower installed capital costs and lower parasitic operating electrical demand, reportedly less than 1% parasitic load. The claim of high SO_2 removal (>98%) is unsubstantiated in the United States, and the potential for reducing SO_3 and other pollutant reductions are under investigation, but generally these FBC claims are believed feasible. Currently, a major concern is their reported module size limitation with current maximums of 500 to 600 MW per module versus wet FGD maximums of 800 to 900 MW. As a result of China's installation of these larger units, operating information is starting to become available for a more systematic evaluation of their actual online performance.

Although the aforementioned technologies are the predominant systems currently applied commercially, other systems are being investigated and tried. For more information on these other technologies, the reader is referred to references published on the U.S. Department of Energy (DOE) and EPA Web sites (www.doe.gov and www.epa.gov, respectively).

Fluidized Bed Combustion

This technology involves directly mixing limestone with coal in the boiler during combustion. The bed of coal and limestone is fluidized by injection of air through the bed. The upward force of air equalizes the downward force of gravity so that the entire bed takes on the appearance of slowly boiling water (Bubenick, Hall, and Dirgo 1981; Roeck 1982; Remick 1985). Limestone is calcined within this combustion environment. The calcined lime that is produced absorbs SO_2 , which is released from coal in the fluidized bed, producing calcium sulfite–sulfate.

Although FBC technology has proven reliable over the last three decades, the process has undergone a technical evolution that has increased both efficiency and the choice of fuels that may be employed. FBC units currently operating around the world use a variety of fuels ranging from high-quality, low-sulfur coal to municipal sludge, sawdust, and coal slag. Normally, utility a nd

industrial boilers use higher-quality fuels, whereas cogeneration facilities, which may have multiple operating objectives, more commonly use alternate fuels.

FBC technology is divided into two primary methodologies: atmospheric and pressurized. The atmospheric FBC units can be subdivided further into bubbling fluidized bed (BFB) and circulating fluidized bed (CFB); the former is the older, more basic technology. BFBs are characterized by low air velocity, relatively thin fuel or reagent bed thickness, and proportionately higher plan area. This technology generally has been restricted to boilers with a steam-generating capacity of less than 100 stpy. Conversely, CFBs operate through the bed at air velocities that are three to four times higher than conventional BFB units. This has the positive effect of decreasing the plan area of the bed; however, at higher velocities, combustion and reagent particles are transported out of the bed with the combustion gases (Kindy 1982; Goldstein, Brown, and Kenney 2003). To utilize these particles and maintain the efficiency of the system, combustion gases pass through an air classifier that removes particles by recycling them back to the combustion bed; hence the name "circulating fluid bed."

FBC technology began its first commercial use in the late 1960s and early 1970s when one of the earliest BFB units was installed at Georgetown University. The technology has gradually grown to the point where several hundred FBC units are now in use in the United States. Figure 1 shows the location of many of these units and provides an indication of the distribution pattern for this technology's application. Although early FBC systems initially were restricted to smaller industrial boilers, advances in CFB technology now allow this system to be used on power generating plants with capacities in excess of 250 MW (Kettunen et al. 2003). Larger units have been permitted in the United States but are not yet operational.

Large generating station designs that utilize FBC systems are turning to pressurized fluid bed combustors (PFBCs). PFBC technology is less well advanced than the atmospheric systems and not as commercialized. Nevertheless, the technology is being employed on a 360-MW unit, the Karita power plant, operated by Kyushu Electric Power Co. in Japan (Koike et al. 2003). In a PFBC unit, the combustion bed thickness is much greater than in an atmospheric system, and the plan area is proportionately less. The increased bed thickness, up to about 4.9 m (16 ft), allows for the same intimate contact between coal and limestone but also may require gradation control on both coal and limestone (DOE 1989b). In the Karita PFBC unit, coal is crushed to about 0.64 cm (0.25 in.) and fines are virtually eliminated. Gas turbine compressors, rather than large forced-air draft fans, provide the combustion air, which is forced into the pressure vessel where combustion actually takes place.

Finally, one of the major advantages of FBC systems is their ability to burn a variety of fuels. For example, 15 medium-sized CFB units in Pennsylvania utilize low-grade reject coal stored in waste piles from decades of high-grade coal production. These stockpiles leak mercury and sulfur into nearby streams and rivers. Unpublished EPA studies recently concluded that CFB units burning coal refuse produce fly ash that captures both mercury and sulfur compounds. Goldstein et al. (2003) discuss the use of coal waste in FBC units, and Jukola et al. (2003) consider new technology designed to increase efficiency when using coal waste. FBC is more than just a means of sulfur capture in combustion gas streams; it also represents an alternate technology in waste-stream recycling and reduction.

RAW MATERIAL REQUIREMENTS

The United States has approximately 97,600 MW of electric generating capacity fitted with FGD scrubbing equipment. It is estimated that these systems utilize approximately 3.6 million stpy of lime

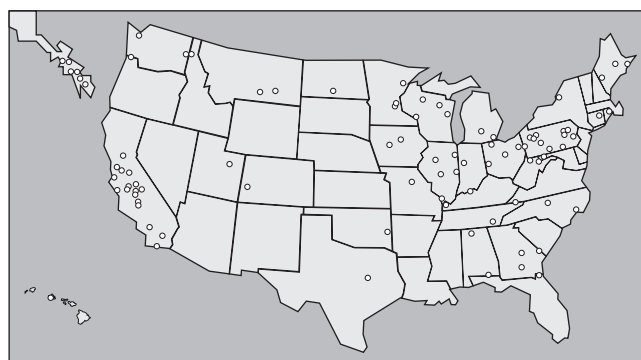

Figure 1. FBC boilers in the United States

and another 8.3 million stpy of limestone. These are estimates of the existing lime–limestone reagent requirements imposed by previous FGD regulations starting in the 1970s and culminating in the 1990 CAAA. This demand for calcium-based reagents was created by reducing 1980 SO₂ emissions of 17.2 million stpy to 10.2 million stpy in 2002, a drop of 41%.

Many forms of air emission legislation are currently being discussed. To put the current situation into perspective, if the Clear Skies initiative of February 2002 moves forward, a 73% further reduction in SO₂ to a 3 million stpy cap by 2018 is envisioned with an intermediate cap of 4.5 million stpy by 2010. Thus, another 7.2 million stpy SO₂ reduction may be in the offing. This does not include any future emission reductions needed for growth in electrical demand over the same time period.

If one assumes the "status quo" on the lime–limestone reagent demand, this 70% additional SO₂ removal translates into an estimated total lime–limestone market of about 6 million stpy lime and 15 million stpy limestone, adjusted for reagent impurities. Timing for this market is largely unknown, but it should occur near the end of the next decade (by 2020).

One of the most basic decisions that the electric utility generating industry must weigh is the cost of transporting coal from the western states to eastern locations versus the cost of additional scrubber requirements imposed by utilizing eastern high-sulfur coal. This is further complicated by the fact that low-sulfur eastern coals could command a premium price. As a result, the utilities must determine the optimum coal sulfur level they can afford to purchase versus the capital cost associated with appropriate scrubber installation and operation. With transportation costs affected by rapidly fluctuating fuel costs, this increases the risk factor in deciding between the choice of coal and corresponding FGD costs.

Not only are technical and commercial issues at play, but the biggest issue may be the politics involved. Deregulation is one major political issue, and when and how this may occur will vary from region to region. A positive outcome could be that power producers will farm out various FGD unit processes to specialists outside the utility industry while retaining close control of the basic "gas path" systems. Thus, the electrical generator owner may realize a more competitive cost picture by subcontracting noncore operations.

FGD Lime and Limestone Reagent Guidelines

The guidelines for lime in FGD are particularly concerned with chemical purity, reactivity, and percentage of insoluble material, about the same as in most other lime applications. The basic chemical requirement for lime is that it must possess the highest possible

NOTE: The lines within the figure represent the upper and lower control limits of limestone used in an FBC unit as specified by three different users.

Figure 2. Representative FBC limestone size distributions

available lime index. Both quicklime and hydrated lime have American Society for Testing and Materials (ASTM) standards to which the FGD system owner or operator can reference when purchasing the lime-based reagent. The measure of available lime also applies to lime systems employing magnesium-enhanced scrubbing. Physical sizing requirements of lime are strictly a material handling and storage issue and should not be linked directly to its chemical parameters. It should be noted that quicklime, or calcium oxide, is a reactive chemical and requires special handling and storage requirements. Additionally, quicklime's affinity for water must be determined for each type of slaking system used to convert calcium oxide into calcium hydroxide, which is the form used in most FGD applications. Lime reactivity together with the slaking equipment choice will affect the particle sizing of the resultant hydroxide particles produced. In general, the smallest particle-size distribution provides the highest surface area, which is usually a big positive for increased reactivity. For more information on lime, the reader is referred to the Lime chapter in this book and to the Web site of the National Lime Association in Arlington, Virginia (www.lime.org).

The chemical requirements for limestone are usually 95% + CaCO_3 , less than 3% MgCO_3 , and minimal inert (SiO₂, Fe₂O₃, Al₂O₃). The "as received" physical sizing specification is mostly a handling issue but also is related to the type of grinding equipment needed to reduce the as-received limestone to a 325 mesh (44 μm) or finer for slurring and increased chemical reactivity. If one is doing the grinding onsite or involved in the grinding decision, another physical or chemical parameter to determine is the Bond Work Index—the power requirement per short ton of raw limestone to grind to 95% –325 mesh (44 μm) or some other defined size. Typically, this value is 10 or less and helps in selecting the type of grinding equipment. The trace flue gas chemical, fluoride, can cause "blinding" of ground limestone in the scrubber's reagent slurry, resulting in higher than normal limestone utilization and lower SO₂ removals.

Physical specifications for FBC are generally much more rigorous, with a narrower range of acceptable particle-size distribution. The reactivity of the limestone may also be a factor in sorbent selection, and the user may also consider limestone porosity. As a result, competitive bids from vendors may be subject to performance quali-

fication on pilot-scale units. The specialized physical specifications for FBC limestone classification generally do not match standard highway specifications for crushed limestone and may result in a higher price for the FBC limestone. FBC units may also have magnesium limitations, generally a maximum of 2% to 3% MgCO_3 .

A typical atmospheric FBC reagent specification normally calls for a high-purity limestone, >95% CaCO_3 , and a very narrow particle-size distribution range such as 30 mesh \times 200 mesh. Figure 2 shows the particle-size distribution curves with upper and lower limits for three CFB units. The CFB manufacturers also specify high-reactivity limestone while at the same time requiring low thermal and mechanical decrepitation during combustion and calcination (Rozelle, Pisupati, and Scaroni 2003). The narrow particle-size distribution has caused some FBC operators to utilize a blended product that may be slightly out of specification at one end of the distribution curve.

The narrow specifications for FBC provide a challenge for reagent suppliers. The narrow size distribution results in a low product yield and a high percentage of fines. These fines are waste unless the limestone producer has an outlet for the –200-mesh material produced. If the supplier produces a limestone product that is significantly outside the specification curve, reagent efficiency will drop precipitously as coarser material falls into the bottom ash and finer particles are blown out with combustion gases.

By-product Materials

By-product materials may be classified into two categories: disposable (throwaway) products and regenerated products.

The waste products from most FGD systems built prior to the 1990 CAAA were disposable. Up until Phase II of the 1990 CAAA, utilities disposed of the vast majority of by-product materials in landfills operated solely for that purpose or in permanent slurry impoundments permitted for that purpose. These surface disposal facilities may include FGD waste products and captured fly ash and bottom ash material. In order to dispose of scrubber by-products in a landfill, the by-products must be rendered stable for an extended period of time. This may be done using materials (lime-based) that induce a pozzolanic (cementitious) reaction. Stabilization is necessary because nonoxidized wet scrubber systems generate by-products that may exhibit thixotropic properties. In any case, the by-product is purely a waste with no commercial value.

Regenerative processes, on the other hand, are designed so that by-product materials can be marketed, thereby reducing overall operating costs of the FGD system. To date, the predominant regenerative system in the United States produces synthetic gypsum used for wallboard manufacturing. To generate an acceptable gypsum product, the scrubber system is designed for forced oxidation that yields a calcium sulfate (gypsum) by-product material. The utility, therefore, must commit itself to producing high-purity gypsum as well as electricity. Although most experience in producing synthetic gypsum through forced oxidation comes from limestone-based FGD systems, wet magnesium-enhanced systems also are able to make commercial synthetic products along with other magnesium-based products.

Not all FGD synthetic gypsum producers are able to sell their by-products because location and economic conditions dictate the commercial feasibility of building a wallboard plant at the site of production. Nevertheless, synthetic gypsum production may offer a better way to "store" or landfill FGD by-products because of its ease in dewatering, improved handling ability, and limited solubility.

Gypsum production is most cost-effective in wet FGD applications. The semidry and dry systems produce a by-product with limited reuse that is ultimately destined for landfill disposal. Some of the potential uses for this dry by-product are associated with

geotechnical engineering or synthetic aggregate production. These semidry and dry FGD by-products may have significant reuse applications, but new research and development needs to be explored to find more economic ways to use these by-products.

CONCLUSION

The 1990 Clean Air Act Amendments have had a significant impact on permissible emissions from new and existing coal-fired boilers in both the utility and industrial markets. This, in turn, has had a major impact on the mining industry.

First and foremost is the impact on the coal industry. The breadth of this is yet to be determined, but some degree of source switching is anticipated. This is expected to have a negative impact on Illinois, Indiana, and Ohio coal producers while having a positive effect on low-sulfur Appalachian and western coal producers. This shift in sourcing and demand is expected to result in pricing changes that, depending on the sulfur content of the coal, may result in either premiums or discounts.

Flue gas desulfurization represents a very real and growing potential market for lime, limestone, dolomite, and other industrial minerals. The size of the market remains somewhat unknown along with its timing. The demand for reagent materials, including the demand from existing scrubbers and those likely to come online between 2005 and 2020, is expected to reach 19 to 20 million stpy by 2020. Even though this is a large market, it is somewhat restricted geographically because of transportation costs and availability of supply. As always, transportation of industrial minerals is a major cost factor and will be no less a consideration in supplying the utility industry with lime and limestone or other products for FGD applications.

Water and Sewage Treatment

Starr Curtis and Ayman El-Midany

INTRODUCTION

There is no doubt that water is the most important fluid to life. It is vital for life on Earth because of its unique properties, which change drastically in the presence of waste materials (e.g., organic, inorganic, heavy metals, dissolved or suspended solids; see Table 1) (Henze et al. 2001). Many minerals and chemicals, some of which are mineral-derived, are used to treat both potable water and domestic sewage wastewater and solids, as discussed throughout this chapter.

The waste materials affect water quality by changing the water's physical, chemical, and biological characteristics (see Table 2). Most of the changes in these properties make the water objectionable to use, especially as drinking water, in addition to their effect from an aesthetic and a health perspective. Moreover, the presence of chemical compounds affects the survival of aquatic life and may corrode or rust metal pipelines conveying water or other materials under water streams.

SOURCES OF WASTEWATER

Contamination comes from different sources, including waste disposal and accidental spills. Common sources of wastes are industrial wastes, sewage disposal systems, municipal landfills, mining and petroleum production, agriculture, urban areas, and saltwater intrusion.

The problem of treating wastewater is increasing daily. Different industries generate large amounts of wastewater; Table 3 lists U.S. wastewater production by industry (Nathanson 2003).

Wastewater is problematic not only because of its quantity but also because of concentrations of harmful constituents in the sewages. Table 4 gives an example of the typical composition of untreated wastewater in the United States.

CONTAMINANTS AND THEIR LIMITATIONS

Table 5 gives the maximum contaminant levels (MCLs) of inorganic chemicals, as determined by the U.S. Environmental Protection Agency (EPA), that can be discarded to free-flowing outlets of a public water system.

In this regard, the American Water Works Association (AWWA) has also set water quality goals. Table 5 shows the EPA MCLs and Table 6 presents the AWWA MCL goals. Achieving the limits of concentrations for each component listed in Table 6 requires treatment. The origin and source of the contaminants in the

wastewater determine the sophistication of the required treatment process.

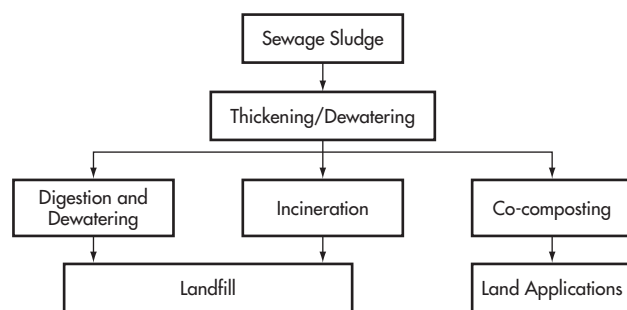

WATER TREATMENT PROCESSES

The primary treatment for wastewater is a separation process that separates the impurities and harmful constituents from the water to allow its reuse. The several types of separation processes used in wastewater treatment can be classified as physical, chemical, or biological treatments. In reality, a combination might be used, but each treatment is described by the predominant removal process—physical, chemical, physicochemical, or biological.

The treatment processes to remove sludge, heavy metals, and radioactive materials are presented in the following paragraphs.

Table 6. AWWA water quality goals

**Figure 1. Sludge treatment alternatives**

Sludge Treatment

Suspended solids from the settling tank or clarifiers in wastewater treatment plants are the main source of sludge. Sludge characteristics differ from one sludge to another. In fact, no two sludges are the same in all aspects, in addition to changes in characteristics with time due to variations in pH, temperature, and so forth.

Sludge has both physical and chemical characteristics. The solid concentrations, volatile solids, and rheological characteristics are physical. The solid concentration determines the behavior of the sludge, its volume, and how it will be handled. Volatile solids are important for the sludge disposal because of gases and odors from the sludge in addition to the concentrations of pathogens. On the other hand, the rheological parameters determine the behavior of sludge under applied forces and are mainly used for scale-up processes.

The chemical composition of sludge is important for using it as fertilizer (which depends on the availability of nitrogen, phosphorus, or potassium). The presence of heavy metal, which comes primarily from industrial waste, determines the toxicity of sludge and consequently controls its usage.

Sludge treatment involves two processes: sludge stabilization and dewatering. The first process reduces or removes the aesthetic problems and noxious odors associated with sludge. The sludge can be stabilized by lime or aerobic or anaerobic digestion. The second process, however, increases the solids content of the sludge and decreases its total volume. Sand beds, filtration, centrifugation, coagulation/flocculation, and sedimentation are among the processes used for sludge dewatering. Several schemes can be used for sludge treatment, and Figure 1 gives treatment alternatives.

MUNICIPAL SOLID WASTE

Municipal solid waste (MSW) consists of all discarded solids and semisolids. Neither hazardous nor radioactive solid materials are

Figure 2. Annual average consumption of U.S. solid wastes (on dry mass basis) for 1980, 1990, and 2000

Hydrogen	2–5
Oxygen	12–24
Nitrogen	0.2–1.0
Sulfur	0.02–0.10

included in the annual average of MSW in the United States shown in Figure 2. The main characteristics of MSW are gross composition, moisture content, particle size, chemical composition, and density. Table 7 gives the proximate and ultimate chemical analyses of MSW.

The MSW is removed by either landfilling or incineration, which converts the waste to other forms no longer detrimental to the environment. The incinerated MSW may also be processed further to yield proven beneficial components (e.g., combustors that can convert water into steam to power heating systems or generate electricity).

Source reduction, reuse, recycling, and composting can divert large portions of municipal solid waste from disposal. Some MSW, however, must still be placed in landfills. Desirable landfill operating practices consist of compacting and covering waste frequently with several inches of soil to reduce odor; to control litter, insects, and rodents; and to protect public health. Many modern landfills are well-engineered facilities that are properly designed, located, operated, monitored, closed, cared for after closure (including remediation when necessary), and financed to ensure compliance with federal regulations.

In the incineration process, shown in Figure 3, combustion converts hazardous waste to less bulky, less toxic material. Carbon

Silica dioxide	SiO ₂	14808-60-7
Sodium carbonate (soda ash)	Na ₂ CO ₃	497-18-8
Titanium dioxide	TiO ₂	13463-67-7
Tricalcium phosphate (hydroxyapatite)	Ca ₅ (PO ₄) ₃ OH	12167-47

* List derived from ANSI/NSF (1988).

[†] The Chemical Abstract Service (CAS), a subsidiary of the American Chemical Society, assigns a unique number to chemical compounds. This CAS Registry Number is widely used for identification on material safety data sheets (MSDSs) and chemical databases.

dioxide, water, and ash are the principal incineration products. If incineration products contain undesirable components, secondary treatment is required (i.e., afterburning, scrubbing, or filtration).

The advantages of incineration as a disposal method are that it is a controlled process; that it is a broadly applicable, well-known process for mixed wastes; and that no large land space is needed. It has some disadvantages, however—the equipment is expensive, complete disposal is not always achieved, and air pollution control technology is required.

Table 9. Chemicals used in potable water processing and their function

Product Function	Chemical Name	Product Function	Chemical Name
Adsorption	Activated carbon	Disinfection and oxidation (continued)	Sodium chlorite
	Alumina		Sodium hydroxide
	Manganese dioxide		Sodium hypochlorite
Algicide	Calcium hypochlorite		Sodium percarbonate
	Copper sulfate		Sodium permanganate
	Sodium percarbonate		Sulfur dioxide
Coagulation and flocculation	Aluminum chloride	Filtration and adsorption	Activated carbon, coal-based
Corrosion and scale control	Aluminum sulfate, alum		Anthracite (coal)
	Bentonite		Diatomaceous earth
	Calcium carbonate		Ferric oxide
	Calcium hydroxide		Ferric oxide/hydroxide
	Calcium oxide		Garnet
	Ferric chloride		Gravel
	Ferric sulfate		Greensand
	Ferrous chloride		Lapis sand
	Hectorite		Perlite
	Kaolinite		Silica sand
	Magnesium carbonate		Zeolite
	Polyaluminum chloride		Zeolite—clinoptilolite
	Polyaluminum silicate sulfate	Fluoride adjustment	Fluosilicic acid
	Silica		Hydrofluosilicic acid
	Sodium aluminate		Sodium fluoride
	Dolomitic quicklime		Sodium fluorosilicate
	Ferrous sulfate		Sodium silicofluoride, sodium fluosilicate
	Calcium carbonate	pH adjustment	Calcium carbonate
	Calcium hydroxide		Calcium hydroxide
	Dipotassium orthophosphate		Calcium oxide
	Disodium orthophosphate		Hydrochloric acid
	Magnesium carbonate		Magnesium hydroxide
	Magnesium hydroxide		Magnesium oxide
	Monosodium orthophosphate		Monosodium orthophosphate
	Phosphoric acid		Potassium carbonate
	Polyphosphoric acid		Potassium hydroxide
	Potassium carbonate		Sodium bicarbonate
	Potassium hydroxide		Sodium carbonate
	Potassium triphosphate		Sodium hydroxide
	Sodium bicarbonate		Sulfuric acid
	Sodium bisulfite	Precipitation	Calcium carbonate
	Sodium carbonate (soda ash)		Magnesium hydroxide
	Sodium hexametaphosphate		Sodium hydroxide
	Sodium hydroxide (caustic soda)	Sequestering	Calcium carbonate
	Sodium polyphosphates, glassy		Magnesium carbonate hydroxide
	Sodium sesquicarbonate		Monosodium orthophosphate
	Sodium silicate		Polyphosphoric acid
	Sodium triphosphate		Potassium triphosphate
	Sodium zinc polyphosphate		Sodium hydroxide
	Sodium zinc potassium polyphosphate		Sodium polyphosphates, glassy
	Sulfuric acid		Sodium silicate
	Tetrasodium pyrophosphate		Sodium triphosphate
	Titanium dioxide		Tetrapotassium pyrophosphate
	Tripotassium orthophosphate		Tetrasodium pyrophosphate
	Trisodium orthophosphate, dodecahydrate		Trisodium phosphate anhydrous
	Zinc chloride	Softening	Calcium carbonate
	Zinc orthophosphate		Calcium chloride
	Zinc sulfate monohydrate		Calcium hydroxide
Dechlorination	Activated carbon		Calcium oxide
	Calcium thiosulfate		Carbon dioxide
	Ferrous sulfate		Potassium chloride
	Sodium metabisulfite		Sodium carbonate (soda ash)
	Sodium bisulfate		Sodium chloride
	Sodium bisulfite		Sodium hydroxide (caustic soda)
	Sodium sulfite	Taste and odor control	Activated carbon
	Sulfur dioxide		Bentonite
Disinfection and oxidation	Calcium hypochlorite		Calcium carbonate
	Chlorine		Calcium hydroxide
	Chlorine dioxide		Copper sulfate
	Hypochlorous acid		Dolomite
	Oxygen, ozone		Potassium permanganate
	Potassium permanganate		

Table 10. Access to improved water supply and sanitation facilities by world region*

Region	Access to an Improved Water Source, %		Access to Improved Sanitation, %	
	1990	2000	1990	2000

Table 11. Water and sanitation progress and goals

Progress between 1990 and 2000	Unfinished Business (as of 2000)	UNICEF Millennium Development Goals (September 2000)
Water: Universal access to safe drinking water		
816 million additional people obtained access to improved water supplies.	<ul style="list-style-type: none"> Some 1.1 billion people still lack access. Global coverage increased by only 3%, to 82%. Water quality problems have grown more severe in a number of countries during the decade. Coverage in low-income areas remains low, especially in informal settlements. 	By 2015, reduce by half the proportion of people without sustainable access to safe drinking water—free from microbiological and chemically hazardous constituents.
Sanitation: Universal access to sanitary means of excreta disposal		
747 million additional people had access to improved sanitation facilities.	<ul style="list-style-type: none"> 2.4 billion people, including half of all Asians, lack access. Global coverage increased by only 5%, to 60%. 80% of those lacking sanitation live in rural areas. 	By 2015, reduce by half the proportion of people who do not have access to basic sanitation.

Adapted from UNICEF 2001.

Potable Water and Sewage Treatment

As mentioned earlier, many minerals and chemicals, some of which are mineral derived (Table 8), are used to treat potable water and domestic sewage wastewater and solids. Table 9 lists the principal processes used in water treatment and the chemicals used in each process. Because lime (as calcium oxide, calcium hydroxide, and dolomitic lime) is the largest chemical (by tonnage) used in water treatment, this chapter deals primarily with this product. Recently, many factors—public health incidents, water shortages, greater “green” awareness, and more numerous or more widely publicized pollution potential for water supplies—have focused scrutiny on water treatment. National and local legislative and regulatory bodies have enacted regulations aimed at conserving and ensuring water quality and at improving and protecting public health. A greater number and variety of treatment processes have increased chemical usage. In recent years, national and international bodies have published specifications for chemicals used in water treatment. Several organizations conduct inspection and testing programs to independently confirm the quality of chemicals offered commercially.

DRIVING FORCES FOR POTABLE WATER AND SANITATION

The availability of safe water and improved sanitation is an indicator of quality of life. Safe drinking water must be free of microbiological and chemical hazards to human health and substantially free of objectionable odors, tastes, and appearance. Improved sanitation

involves disposing of human excreta by means of a facility or method that isolates or destroys disease organisms. Access to safe drinking water and improved sanitation treatment varies widely around the world (Table 10).

Although there has been progress in providing safe drinking water and improved sanitation around the world, the UNICEF assessment and goals for improvement show how far there is to go (Table 11).

POTABLE WATER TREATMENT

Regulatory Framework

The goal of potable water treatment is to reliably convert available raw water to an affordable, consistent, stable, palatable water supply that is free of infectious agents, toxic impurities, and objectionable tastes, odors, and turbidity. Legally enforceable drinking water standards limit the maximum allowable levels of specific impurities in public water supplies. These are generally based on WHO's *Guidelines for Drinking-Water Quality* (WHO 2004), reflecting scientific knowledge available and the principle that water intended for human consumption can be consumed safely on a life-long basis.

In the United States, the EPA regulates 87 parameters in the Primary Drinking Water Standards (EPA 2003) under the authority of the Safe Drinking Water Act (SDWA), which was passed in 1974 and amended in 1986 and 1996.

The European Union regulates 48 parameters in standards promulgated as Council Directive 98/83/EC (EUROPA 2003) on

Table 12. Potable water treatment

Treatment Step	Function
Screening	Removes coarse particulate matter
Coagulation and rapid mixing	Adds treatment chemicals that attract and bind fine particulate matter
Flocculation	Promotes the growth of the particles binding the fine impurities
Sedimentation	Allows the flocculated particles to precipitate or settle out of the treated water
Filtration	Removes the fine particles remaining after the sedimentation process and yields turbidity-free water
Disinfection	Kills any organisms that remain in the water or treatment system and maintains, if appropriate, a residual disinfection capacity for the distribution system
Storage and distribution	Stores and distributes the treated and disinfected water to users in a manner that preserves its purity and safety

Table 13. Summary statistics of softening plants in the United States by process

Softening Process	Number of Plants	Average Daily Production, mgd	Total Daily Production, mgd
Softening	353	0.85	299
Coagulation-softening	265	8.50	2,246
Softening-iron removal	366	0.95	348
Coagulation-softening-iron removal	45	3.60	162

the quality of water intended for human consumption, which has updated and replaced the Drinking Water Directive of 1980.

Treatment Processes

Treatment processes have been developed to remove or inactivate raw water components that may be hazardous to human health. The principal steps of most water treatment processes (Table 12) may use several chemicals (Table 9). Some water suppliers (principally those whose source is groundwater or low-turbidity surface water) omit the sedimentation step, and so their treatments are called direct filtration processes.

Newer membrane processes are increasingly important in potable water treatment, particularly in desalination of brackish or seawater. Synthetic membrane filters exclude particles down to the size of ions while passing water molecules by means of pressure. Treatment chemicals can be used in pre- or posttreatment steps to increase the efficiency and economy of the process and to extend the life of the membranes.

Drinking Water Treatment Chemicals

Many chemicals find use in processes to convert a raw water resource to a potable water supply that meets the prevailing water quality standards. The purity of chemicals used in potable water treatment is subject to governmental regulations. In the United States, drinking water treatment additives must comply with the ANSI/NSF Standard 60, *Drinking Water Treatment Chemicals*, which “establish(es) minimum requirements for the control of potential adverse human health effects from products added to water for its treatment” (ANSI/NSF 1988, p. v.). “This standard covers products intended to be added to water in the production of drinking water for such purposes as: disinfection, oxidation, filtration, scale control, corrosion control, pH adjustment, softening, precipitation, sequestering, fluoridation, coagulation, flocculation,

or miscellaneous treatments, including water well products” (ANSI/NSF 1988, p. 1). The purity criteria for water treatment chemicals are determined by the amounts of impurities contributed to the product water from the maximum treatment dosage of the treatment chemical. The impurity limits of the drinking water standards, the maximum treatment chemical dosage, and a safety factor determine the maximum allowable contribution of impurities from the treatment chemicals.

Water Softening

Lime use in water treatment primarily involves water softening, where it reduces carbonate hardness caused by dissolved bicarbonate and carbonate compounds. Currently there are more than 1,000 domestic water softening plants (Table 13) in most sections of the country, but particularly in the midwestern states, in Florida, and in Texas, where limestone bed rock abounds (ASCE/AWWA 1990). Among the other uses for lime in water treatment are coagulation, disinfection, and removal of heavy metals due to high pH softening; removal of certain radioactive and organic compounds and fluorides; neutralization of acidic water; removal of silica, particularly with dolomitic lime; and removal of color. Most of the above advantages accompany water softening, although at some plants lime is used specifically for one purpose, such as silica removal with dolomitic lime, minimizing pipeline corrosion by addition of lime to correct aggressive water, and others.

Hardness in water comprises two types—carbonate hardness, caused by dissolved calcium and magnesium carbonates and bicarbonates; and noncarbonate hardness, caused by dissolved noncarbonate salts, particularly calcium sulfate, calcium chloride, magnesium sulfate, and magnesium chloride. Total hardness is the sum of the carbonate hardness and noncarbonate hardness. Waters are classified as soft (0 to 75 mg/L as CaCO₃), moderate (75 to 150 mg/L), hard (150 to 300 mg/L), and very hard (above 300 mg/L). Most water plants strive to reduce total hardness to about 100 mg/L, although in recent years the tendency in some cities has been to allow a little higher value to reduce both chemical costs and the amount of water softening sludge produced.

There are four basic types of softening plants: lime softening, primarily to reduce carbonate hardness; lime-soda softening, for reduction of both types of hardness (in some plants caustic soda is used in place of soda ash, but it is more costly); split lime-zeolite, where a base exchange mineral is employed in place of soda ash (this system also requires sodium chloride to regenerate the zeolite mineral); and finally, zeolite softening, which is generally used in small systems for private residences and small municipalities. The principal disadvantages of the last system are its relatively high cost and the salt requirement, which introduces considerable quantities of soluble salts into the wastewater discharge system.

Lime neutralizes carbon dioxide, forming calcium carbonate, a precipitate, to convert soluble bicarbonate to calcium carbonate, and also to precipitate magnesium hydroxide. The following reactions occur in lime softening:

Reactions involving soda ash are as follows:

The principal by-product formed is calcium carbonate, a filterable insoluble precipitant referred to as water softening sludge. The quantity is large, as indicated by the fact that in precipitating the calcium ion, Equation (2), two moles of calcium carbonate are formed for every mole of calcium ion removed from the water. In large plants, the sludge is voluminous and often presents a disposal problem. Generally, the sludge is placed in a lagoon, or it may be dewatered with vacuum filters, belt and filter presses, or centrifuges, and then disposed of on farm fields as an agricultural liming material. Its high calcium carbonate content and fineness enhance its value as a liming material. Another use is as a neutralizing chemical in industrial and sewage treatment plants. A few large municipal plants have successfully recycled the sludge by dewatering and then calcining the material in rotary or fluidized kilns to produce quicklime for reuse at the softening facility.

After lime softening, the pH and alkalinity of the treated water must be adjusted to a level suitable for human consumption. Often a small stream of raw water is mixed with the treated water to achieve the desired alkalinity level, requiring further sterilization.

The finished water must be nonaggressive (noncorrosive) to the distribution system and also must not scale. To achieve this balance, the pH and alkalinity must be adjusted. Tools such as the Langelier index can determine the aggressive nature of the water. Recarbonating the treated water with CO_2 gas can often achieve the desired pH and alkalinity.

Formation of some protective scale is often desirable, but care must be taken to ensure that excessive scale and decreased flow levels are not induced. A thin calcium carbonate scale will protect the water from the dissolved salts of heavy metals, iron deposits (red water), and objectionable taste. Several specialty chemicals such as glassy polyphosphates are used to ensure a protective coating without excessive scaling.

Coagulation

Because many water supplies, particularly river water, contain suspended solids, it is usually necessary to add coagulants to remove turbidity. The principal coagulants are aluminum sulfate (alum), ferric chloride, ferric sulfate, polyaluminum salts, and lime. Lime is also used for pH control with the other coagulants. The optimum pH for alum is 5.5 to 7.5 (typically 7.0) and for the ferric salts, 5.0 to 8.5 (typically 7.5). Because many waters are acidic in nature, lime is nearly always used to raise the pH to attain the optimum coagulation efficiency; small plants often use liquid caustic soda instead of lime.

In recent years, various polyelectrolytes have been developed for use as coagulants, either alone or with the above metal ion coagulants. In many cases, lime is also used with certain polyelectrolytes. In the coagulation step, the lime is generally added with the coagulant chemical, although it often may be advantageous to add the lime ahead of the coagulant. Besides providing the proper pH, lime also acts as a filter aid, particularly with gelatinous-like sludges formed with certain water and coagulant combinations that are difficult to filter.

Purification

Research as far back as 1913 (Riehl 1962) indicated that treatment with excess lime (to pH 11+, with holding times of 24 to 48 hr) destroys *Escherichia coli*. More recent research confirmed these earlier findings, and work has also been extended to other bacteria,

Table 14. EPA's hazardous waste groups

Hazard Classification	Type	Category	Examples
Source	Specific	F	Halogenated and nonhalogenated solvents, electroplating sludge
	Nonspecific	K	Oven residue, brine modification muds
Level	Acute	P	Arsenic oxide, potassium silver cyanide, and toxaphene
	Regular	U	Carbon tetrachloride, DDT, and xylene
Others			Exhibits ignitability, corrosivity, reactivity, or toxicity

viruses, parasites, and parasite eggs. Sterilization is attributed to physical absorption of the pathogens on the flocs that settle out following the lime softening-coagulation reaction and the destruction of pathogens by the high pH. According to Boynton (1980), a serious epidemic of infectious hepatitis in Bombay, India, which was traced to the potable water supply, was stopped using excess lime treatment to a pH of 11+. Despite encouraging experience with lime sterilization, however, it can never fully replace chlorine as a disinfectant because the latter's residual content protects against later contamination in the water distribution system.

Removal of Heavy Metals and Radionuclides

Radioactive wastes can be a product of fuel cycles in nuclear power plants, nuclear weapons and their manufacturing, radiopharmaceutical manufacture and use, biomedical research and application, and a number of other industrial uses. The common and important radionuclides are krypton-85; strontium-90; iodine-131; cesium-137; tritium; cobalt-60; carbon-14; uranium-235 and 238; and plutonium-239. The treatment of the radioactive wastes is still a challenge because of the long decay times and the required disposal site specifications.

In the United States, nuclear power plants supply 20% of electricity (Weiner and Matthews 2003). In the late 1990s, shutting down the U.S. nuclear industry was seriously considered. But the electricity shortage in California in 2000–2001 may play an important role in the acceptability of nuclear energy because no large-scale alternative energy sources have been established (i.e., wind power, solar power, etc.).

On the other hand, hazardous wastes are harmful for the environment and for life, and they cannot be handled or disposed of without special precautions. The EPA has grouped hazardous waste into five categories, which are listed in Table 14. Table 15 lists the maximum allowable concentrations of hazardous waste (40CFR261.24), and Figure 4 shows the commercial disposal technologies used.

Table 16, based on EPA data summarized from various research studies involving laboratory or pilot-scale experiments, indicates that a variety of heavy metals, including arsenic, barium, cadmium, chromium, fluoride, lead, mercury, silver, and others, can be removed from potable water by raising the pH from 6 to 11, depending on the metal involved (ASCE/AWWA 1990). These data are based on conventional treatment involving coagulation with alum or iron salts, followed by lime or lime-soda softening. Treatment steps include mixing, flocculation, sedimentation, and filtration. The elevation in pH precipitates the metals out of solution for ready removal. As noted, the pH elevation occurs during lime or lime-soda softening or coagulation with alum or ferric salts abetted by lime addition. The mechanism of removal for inorganic contaminants may be precipitation of insoluble metal hydroxides, carbonation, coprecipitation with iron or aluminum hydroxides, or adsorption with natural turbidity or on floc particles formed during the reaction.

Table 15. RCRA hazardous waste limits by toxicity characteristic (TCLP)

Contaminant	Chemical	Maximum Concentration, mg/L
Arsenic	As	5.0
Barium	Ba	100.0
Cadmium	Cd	1.0
Chromium	Cr	5.0
Lead	Pb	5.0
Mercury	Hg	0.2
Selenium	Se	1.0
Silver	Ag	5.0
Endrin	1,2,3,4,10,10-hexachloro-1,7-epoxy-1,4,4a,5,6,7,8,8a-octahydro-1,4-endo, endo-5,8-dimethano naphthalene	0.02
Lindane	1,2,3,4,5,6-hexachlorocyclohexane, gamma isomer	0.4
Methoxychlor	1,1,1-trichloro-2, 2-bis[p-methoxyphenyl] ethane	10.0
Toxaphene	C ₁₀ H ₁₀ Cl ₈ , technical chlorinated camphene, 67–69% chlorine	0.5
2,4-D	2,4-dichlorophenoxyacetic acid	10.0
2,4,5-TP Silvex	2,4,5-trichlorophenoxypropionic acid	1.0

NOTE: Treatments include physical, chemical, and biological.

Figure 4. Commercial disposal technologies for hazardous material**Table 16. Summary of treatment processes for inorganic contaminants**

Contaminant	Process	pH Range	Comments
Arsenic +5	Ferric sulfate coagulation	6–8	NA*
	Alum coagulation	6–7	NA
	Lime softening	>10.5	NA
Arsenic +3	Ferric sulfate coagulation	6–8	Oxidation to As ⁵⁺ by chlorination required prior to coagulation
	Alum coagulation	6–7	
	Lime softening	>10.5	
Barium	Lime softening	10–11	NA
	Ion exchange	NA	Normal cationic exchange resins effective
			Effective over full lime-softening range
Cadmium	Ferric sulfate coagulation	7–8	
	Lime softening	NA	
Copper	Stabilization and corrosion control	Site-specific	NA
Chromium +3	Ferric sulfate coagulation	6–9	NA
	Alum coagulation	7–9	NA
	Lime softening	>10.5	NA
Chromium +6	Ferric sulfate coagulation	7–9.5	NA
Fluoride	Ion exchange	Neutral pH recommended	Ion-exchange media: activated alumina or bone char
	Lime softening	>11	Fluoride coprecipitates with magnesium hydroxide, high magnesium required
Lead	Ferric sulfate coagulation	6–9	NA
	Alum coagulation	6–9	NA
	Lime softening	NA	Effective over full lime-softening range
Inorganic mercury	Stabilization and corrosion control/ferric sulfate coagulation	Site-specific, 7–8	NA
Organic mercury	Activated carbon	NA	Powdered and granular carbon effective
Nitrate	Ion exchange	NA	Ion-exchange media: strong base resin
Radium	Lime softening	NA	Effective throughout entire softening range
	Ion exchange	NA	Normal cationic exchange media effective
	Reverse osmosis	NA	NA
Selenium +4	Ferric sulfate coagulation	6–7	NA
	Ion exchange	NA	Ion-exchange media: strong base resin or activated alumina
Selenium +6	Reverse osmosis	NA	Alumina
	Reverse osmosis	NA	NA
Silver	Ferric sulfate coagulation	7–9	NA
	Alum coagulation	6–8	NA
	Lime softening	NA	Effective over full lime-softening range
Zinc	Stabilization and corrosion control	Site-specific	NA

* NA = not applicable.

Figure 5. Removal of inorganic contaminants by lime softening

Figure 6. Lime-soda process: total hardness removal fraction versus radium removal fraction

Table 17. Efficiency of dissolved solids removal treatments

Removal Process	Dissolved Solids					
	Suspended Solids	Oxygen Demand		Nitrogen Compounds		
		BOD ₅	COD	Ammonia (NH ₃)	Organic Nitrogen (N)	Phosphate (PO ₄)
Activated carbon adsorption	80–90	70–90	60–75	—	50–90	—
Ion exchange	—	40–60	30–50	85–98	80–85	85–98
Electrodialysis —	—	—	—	30–50	—	30–50
Reverse osmosis	95–98	95–99	90–95	95–99	95–99	95–99

Figure 5 shows the extent of removal of various inorganic contaminants by lime softening, based on a pH of 8 to 12 (ASCE/AWWA 1990). Note in particular that lead and cadmium are completely removed at pH 8, arsenic+5 and chromium+3 at pH 11, and barium at pH 10. Other metals show substantial removal at elevated pH.

Radium, an alkaline earth material chemically similar to calcium and barium, is removed during lime softening and generally not during coagulation. Removals of 70% to 95% have been reported, with greater removals occurring with greater hardness removals (Figure 6) (ASCE/AWWA 1990). Generally, the higher the pH during softening, the greater the radium removal.

Neutralization of Acid Water

The growing concern about the presence of lead in drinking water has increased the use of lime for neutralizing slightly acid water. Raising pH to >7 prevents the dissolution of solder lead in pipe fittings. Further, lime corrects corrosive waters with excess CO₂ by absorption of the gas, forming a thin calcium carbonate deposit on the inside of the pipes.

Silica Removal

Waters containing silica are especially harmful in high-pressure boilers and turbines because of the formation of troublesome scale on the pipes and turbine blades. When dolomitic lime is used in the softening process, much of the silica is removed by its reaction with magnesium oxide and hydroxide.

Removal of Other Impurities

Lime is also used to help remove various other impurities, especially manganese, fluorides, iron, and organic tannin, which cause undesirable colors. Generally, lime softening will remove 80% to 90% of the color, and activated carbon removes the balance.

SEWAGE WASTEWATER TREATMENT

The goal of wastewater treatment is to safely collect, treat, and dispose of human excreta in a manner to prevent spread of disease and return the treatment processes to productive use. The principal methods of sewage treatment involve a number of steps:

1. Collection of the waste
2. Conveyance in a confined manner to a treatment facility
3. Separation of the solid wastes from the liquids
4. Treatment of liquids
 - a. Reduce the pathogen content and nutrient content. Biological growth media are commonly used to promote a non-pathogenic biological community which cannibalizes the pathogens.
 - b. Remove the biological component by clarifiers and filters. The biological sludge is usually treated with the solid waste stream.
 - c. Disinfect the treated water for safe discharge or reuse.

Figure 7. Treatment efficiencies for removal/destruction of bacteria in wastewater

5. Treatment of solids

- a. Reduce the volume and pathogen levels of the solids wastes. Incineration, drying (natural or artificial), and aerobic and anaerobic digesters are commonly used in large installations.
- b. Isolate, dispose of, or reuse the disinfected residual solids in a safe manner.

Table 17 describes the removal efficiency of several treatments to remove dissolved solids, and Figure 7 charts the efficiency of treatments to remove or destroy bacteria.

Fertilizers

William C. Herz and Harry L. Vroomen

INTRODUCTION

Plants obtain nutrients from both air and soil, and nutrient balance is vital to soil fertility and crop production. Plants absorb carbon dioxide (CO_2) mainly from the air, although some CO_2 may be dissolved in soil water that is absorbed by plant roots. CO_2 , a gaseous form of carbon and oxygen, supplies the carbon that usually makes up 50% or more of plant structure. It is important to recognize that many factors control soil productivity and fertilizer use is only one of them. Fertilizers are most effective when overall attention is paid to the nutrient balance of the soil and all required nutrients are present in correct ratios.

Growing plants use water more than any other biological substance. Plant nutrients dissolve in soil water and enter the plant via root absorption. Water is then given off into the air as the plant breathes or transpires. Water also supplies hydrogen and oxygen to plants. Plant roots absorb nutrient cations or anions by contact exchange with soil clay particles. In terms of fertilizer/water interaction, appropriate fertilization can help prevent stresses resulting from low-water years. In fact, appropriate fertilization will increase yields in wet or dry weather (water use efficiency).

Inorganic or mineral nutrients essential to plants are supplied through the soil. The inorganic or mineral composition of plants is usually less than 5% of their weight. In most crop-growing areas, much of this nutrition is inadequately supplied from soil reserves and must be provided by fertilizers. The role of the fertilizer industry is to supply economical, efficient, good-quality fertilizers to improve or maintain soil productivity for optimum crop production.

Other than carbon, hydrogen, and oxygen, the essential plant nutrients that must often be added to soils or plants are categorized as primary nutrients (nitrogen [N], phosphorus [P], and potassium [K]); secondary nutrients (calcium, magnesium, and sulfur); and micronutrients (boron, chlorine, copper, iron, manganese, molybdenum, and zinc). These classifications, which are based on the quantity of nutrients utilized by plants, do not imply their function or degree of necessity.

Much attention has been paid recently to the environmental impact of fertilizers and nutrients in the environment in general. In response, the science of fertilizer application and management practices in general are evolving to integrate a sophisticated suite of practices called best management practices (BMPs). These practices may include the use of advanced fertilizer products such as slow- or controlled-release fertilizers; soil testing; precision agriculture; and

the use of crop rotation, buffer strips, or other site-specific practices as needed to prevent unintended release of nutrients to the environment.

AGRICULTURAL PRODUCTION AND PLANT NUTRIENT USE

Until about 1900, demands for higher crop yields were met simply by bringing new agricultural lands into cultivation. Since that time, great progress has been made in increasing yields through fertilization and improved crop varieties and cultural practices. At the same time, land under cultivation throughout the world has remained relatively constant or, as in the United States in recent years, has been taken out of production. Figure 1 illustrates the relationship of agricultural production to crop acreage and consumption of the primary plant nutrients in the United States since 1965. This figure demonstrates the great increases in productivity accomplished with declining levels of cropland over the past several decades.

In the past 40 years, particularly during the 1980s and 1990s, the growth of the U.S. fertilizer industry has been relatively stable. In 1962, U.S. farmers used 24.1 Mt of fertilizer materials at a total expenditure of \$1.5 billion. In 1990, total fertilizer consumption exceeded 43.2 Mt, valued at more than \$7 billion. Table 1 indicates farm expenditures and plant nutrient consumption in the United

States from 1960 to 2000. Phosphate and potash are expressed as P_2O_5 and K_2O , respectively. To convert phosphate to phosphorus, multiply P_2O_5 by 0.44 and multiply K_2O by 0.83 to convert to potassium.

Food demand for a growing world population stimulated crop production in the United States during the 1960s and 1970s. Farmers rapidly expanded plant nutrient application rates in an attempt to increase crop production and farm income. Then, as farm commodity prices fell in the face of overproduction, farmers began to reduce application rates. Crop yields have continued to set new records, however, as farmers have increased the efficiency of fertilizer use through improved soil fertility and management practices. Figure 2 illustrates the pattern of U.S. plant nutrient application rates for corn over the past four decades. This figure also shows that nutrient consumption in the United States was remarkably stable during the period from 1980 to 2000.

As application rates of phosphorus and potassium have declined in recent years, crop removal of these nutrients is depleting the nutrient supply in some soils. With the current emphasis on sustainability in agriculture, nutrient removal will become a critical factor in future crop production. Figure 3 illustrates the change in nutrient removal ratios for the United States from 1965 through 2000. A value greater than 100% indicates that more nutrient is being removed from the soil than is being added. The figure clearly demonstrates that macronutrient withdrawal is significantly exceeding input, especially for potash, a situation that will ultimately result in deficits over time.

In March 2004, the world population was greater than 6.35 billion people. The widespread forecasts of food shortages and famine that were predicted in earlier years have not come to pass. Although population estimates for 2050 range from approximately 9 billion to almost 12 billion, world per capita food production has kept pace with population growth and diets have steadily improved (see Figure 4). There may always be pockets of limited food supplies, but with the proper use of fertilizers and other agricultural inputs, the success of world agriculture will continue. Fertilizer has been and will remain the keystone to adequate food and fiber production in the coming years.

PRIMARY PLANT NUTRIENTS IN FERTILIZERS

Primary nutrients (nitrogen, phosphorus, and potassium) are designated as such because of the amounts required and their significance to plant growth. Practically all soils are deficient in nitrogen. Most soils are also deficient to varying degrees in available phosphorus and potassium. Consequently, these nutrients comprise the vast majority of fertilizers applied to soils.

Nitrogen

Nitrogen is part of every living cell and is essential for plant growth. Plants require large amounts of nitrogen for normal growth. Adequate nitrogen is also important for water use efficiency. The use of nitrification inhibitors or slow-release formulations of nitrogen can improve the efficiency of nitrogen use. Nitrogen fixation must occur before nitrogen can be used by plants, and most forms of nitrogen will increase soil acidity.

The world needs a tremendous amount of protein, and sound agronomic practices including the use of nitrogen fertilizers can help fulfill the protein requirement of higher yielding, more protein-rich crops. Using an assumption of 40 g (1.4 oz) of protein per person per day for the entire world population, daily consumption would be approximately 545 million lb and annual consumption would be greater than 100 Mtpy.

Nitrogen accounts for about half of the total nutrients applied as fertilizers in the United States. Table 2 shows consumption of nitrogen fertilizer in North America and other world markets in recent years, and Table 3 lists the International Fertilizer Industry Association's (IFA) statistical classifications for regions and countries. North America and Western Europe have decreased in importance in the world market as fertilizer use has increased dramatically in eastern Europe and Asia in the past decade. In 2000, Asia accounted for 43% of world nitrogen use, followed by North America at 12%.

The manufacturing process for nitrogen fertilizers involves the fixation of atmospheric nitrogen through a chemical process called the Haber-Bosch equation. Commercially available sources of nitrogen include both organic and inorganic forms. Nitrogen is mainly

absorbed from the soil by plants as nitrate (NO_3^-), but may also be taken up as ammonium (NH_4^+) ions, and all nitrogen must be converted to these forms before it can be absorbed by the plant. After entering the plant, nitrogen is converted into complex compounds and ultimately into proteins.

In the past, virtually all nitrogen was applied to soil in the form of animal manures. Certain soils in Europe have a synthetic surface layer more than 0.9 m thick resulting from centuries of manure application. One of the earliest commercial sources of nitrogen was guano (excreta and remains of sea fowl found in deposits on certain arid islands). This material can contain as much as 13% nitrogen and about 9% phosphorus. Neither manure nor guano is an important commercial source of fertilizer today, although environmental regulation of large animal operations will likely increase the importance of manure utilization. In fact, several state-of-the-art pilot plants that convert poultry litter to commercial fertilizer have been built. Animal manures are applied to soils primarily because of the need for disposal, but manures may supply significant amounts of nitrogen to fields near their source of origin. It is important to note that organic nitrogen comprises 97%–98% of the nitrogen found in soil. This form of nitrogen cannot be used by plants but is gradually transformed by soil microorganisms to ammonium. Ammonium is not leached to groundwater to a great extent. Because ammonium is a positively charged ion (cation), it is attracted to and held by the negatively charged soil clay, making it available to plants.

Commercially important inorganic sources of nitrogen include ammonium nitrate (NH_4NO_3), available in both solid (33%–34% N) and liquid (19%–21% N) forms; ammonium sulfate [$(\text{NH}_4)_2\text{SO}_4$, 21% N]; calcium nitrate [$\text{Ca}(\text{NO}_3)_2$, 15% N]; potassium nitrate [KNO_3 , 13%–15% N]; urea (NH_2CONH_2 , 45%–46% N); anhydrous ammonia (NH_3 , 82% N); and nitrogen solutions (28%–32% N), a combination of ammonium nitrate and urea solutions. Figure 5 shows the relative importance of these products in the United States. Worldwide, urea has become the leading nitrogen fertilizer because of its high nutrient content and applicability to most crop management practices.

Nitrogen is applied to soils either before planting, at planting, or after planting as a side dress application. All inorganic sources of nitrogen convert to the usable nitrate form rather rapidly in warm, moist soils, but nitrates may leach rapidly under certain conditions. The crop, soil, and weather conditions dictate which materials and application methods are best, but some general principles are applicable. Soil conditions that have the greatest influence on nitrification or denitrification include soil pH, moisture content, temperature, aeration, and amount of plant residues in the soil. Leaching can contribute to ground water and surface water pollution. Loss of nitrates by leaching is undesirable from all standpoints. The loss is minimized and crop use maximized by the following proper management practices:

- Split the applications of nitrogen on sandy or shallow soils where leaching or erosion hazards are greatest and when heavy rates of nitrogen are required.
- Apply nitrogen during the growing season on soil subject to leaching and erosion.
- Apply the proper amount of nitrogen and other plant nutrients for vigorous crop growth; base this amount on a soil test.
- Use good soil conservation techniques to minimize erosion losses of topsoil.

Phosphorus

Phosphorus is essential for normal growth and maturity. It plays a role in photosynthesis, respiration, energy storage and transfer, cell division, cell enlargement, and several other processes in plants. Adequate phosphate also has many other beneficial properties, including helping roots and seedlings develop more rapidly, improving winter hardiness, increasing water use efficiency, contributing to disease resistance in certain plants, and hastening maturity—all important to harvest and crop quality. Of the three primary nutrients in fertilizers, phosphate is required by plants in quantities about one tenth as high as those of nitrogen and potassium. In 2000, total phosphate used in the United States was approximately 4.5 Mt. World consumption of phosphate has been level over the last 25 years; from 32.03 Mt in 1980 to 32.48 Mt in 2000 (Table 4).

Phosphorus is absorbed from soils by plants principally as the orthophosphate (H_2PO_4^-) ion. Once inside the plant, it enters into the composition of phospholipids and nucleic acids. A major metabolic role of phosphorus in the cells of both plants and animals is the provision of energy that results from the high-energy phosphate bonds. In the growing plant, phosphorus is most abundant in growing tissues where it is utilized in the synthesis of nucleoproteins. As the plant matures, phosphorus accumulates in the seed and fruit.

Fertilizer phosphorus is highly reactive with clays and organic constituents in soils and forms relatively insoluble compounds. As a result, it does not move downward with percolating groundwaters but tends to accumulate in the surface layer of soil. Thus, after several years of high phosphorus fertilization, farmers are able to reduce their phosphorus fertilization rates without loss in crop yields. High crop yields, however, usually require a maintenance application of phosphate fertilizer.

The development of the modern phosphate fertilizer industry dates back to 1840 when Justus van Liebig, a German scientist, demonstrated that the fertilizer value of bones was significantly increased by treatment with sulfuric acid. Two years later, the process by which phosphate rock (apatite) was treated with sulfuric acid to produce ordinary superphosphate (20% P_2O_5) was patented in England by John Bennett Lawes. Commercial production began in the United States in 1852.

Source: AAPFCO and The Fertilizer Institute 2003 and earlier issues.

Figure 5. Consumption of selected nitrogen materials

In today's fertilizer phosphate industry, nearly all products originate from phosphate rock. It is still acidulated with sulfuric acid using essentially the same principle employed in England more than 100 years ago. Ordinary superphosphate dominated the phosphate market until recent years when new materials began to replace it, primarily because of their higher phosphate content and lower transportation costs. The three products currently dominating the world phosphate market include normal superphosphate [$\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O}$], concentrated superphosphate [$\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O}$], and complex fertilizers including monoammonium phosphate ($\text{NH}_4\text{H}_2\text{PO}_4$); di ammonium phosphate [$(\text{NH}_4)_2\text{HPO}_4$]; and nitric phosphates of varying analyses. Figures 6 and 7 illustrate how the production of ammonium phosphates has grown since its introduction in the U.S. fertilizer market in the 1950s.

Nearly all commercially available sources of phosphorus are highly water soluble. However, when the calcium phosphates, such as normal superphosphate, are ammoniated to make other complex fertilizer products, the high pH of the manufacturing process often causes further reaction of calcium with the phosphorus, resulting in precipitation of insoluble calcium phosphate compounds. These products are more effective on acid soils than on alkaline soils.

Most crops recover only 10%–30% of mineral phosphorus during the first year following application. Overall recovery can vary widely, depending on phosphorus source and a number of other variables, but much of the residual phosphorus will be available to succeeding crops. Other important considerations in phosphorus application to soil and its utilization by plants is soil pH. The soil pH range for optimum phosphorus availability is 6.0 to 7.2. In more acid soils, phosphorus can be complexed by iron and aluminum compounds. At alkaline pH levels, phosphorus reacts with calcium, forming insoluble calcium phosphates. These problems are partially overcome by liming acid soils and applying only highly water-soluble phosphate sources on alkaline soils.

Because of its relative immobility in soils, phosphorus must be incorporated into the soil for optimum effectiveness. Broadcasting phosphate fertilizers with subsequent incorporation is an effective method of application. Recovery of applied phosphorus is usually higher, however, when it is placed in a band beside the seed row, particularly when a available soil phosphorus levels are quite low. At low rates, some phosphate fertilizers have been effectively applied in direct contact with the seed. Broadcasting still dominates phosphorus fertilizer application in the United States, but band application at seeding continues to grow in importance, especially with the use of liquid phosphate materials.

Figure 6. Consumption of selected phosphate and potash materials

Potassium

Potassium is one of the vital three primary nutrients, along with nitrogen and phosphorus. Primary minerals generally considered to be the original sources of potassium include orthoclase and microcline feldspars, muscovite, and biotite. Many high-yield crops have potassium contents that exceed their nitrogen content. Potassium is vital to photosynthesis, and when deficient, photosynthesis declines and the plant's respiration increases. The deficiency symptoms lower the plant's carbohydrate supply. The potassium content of fertilizers is expressed as K_2O equivalent, or potash, even though no K_2O exists as such in fertilizer materials. To convert from K to K_2O , multiply by 0.83.

From 1960 to 2000, world potash consumption increased by more than 250%. Table 5 shows that it increased from 8.48 to 21.86 Mt during this period. From 1980 to 2000, however, world consumption changed little. Muriate of potash (potassium chloride, or KCl) is the dominant source of fertilizer potassium throughout the world. Other important, but much less significant, sources are sulfate of potash (K_2SO_4), potassium magnesium sulfate ($K_2SO_4 \cdot MgSO_4$), and potassium hydroxide (KOH).

Growing plants absorb potassium as the K^+ ion. Potassium is unlike the other mineral constituents in that its exact metabolic role

Source: AAPFCO and The Fertilizer Institute 2003 and earlier issues.

Figure 7. Consumption of selected phosphate materials

in the plant is unknown. It occurs in the ionic state and not as a component of compounds within the plant, but potassium is indispensable for plant growth and most plants require it in large quantities. Some known functions of potassium include the following:

- It is essential to protein synthesis.
- It breaks down carbohydrates, a process that provides energy for plant growth.
- It helps to control ionic balance and provides turgor; potassium-deficient plants wilt more easily.
- It helps the plant overcome the effects of disease and improves winter hardiness.
- It activates more than 80 enzyme systems that regulate the rates of major plant growth reactions.

Potassium and phosphorus application methods are very similar. Most potassium is broadcast, with a lesser amount band-applied near the seed row at planting time. Muriate of potash is usually mixed with phosphorus fertilizers and the two nutrients are applied simultaneously to soils. Almost two thirds of the potassium used in the United States is applied to soils of the Corn Belt in the Midwest.

SECONDARY PLANT NUTRIENTS IN FERTILIZERS

Although plants require calcium, magnesium, and sulfur—the secondary micronutrients—in smaller amounts than the primary nutrients, their role in plant nutrition is easily as important as that of the primary nutrients. Many crops contain as much sulfur (S) as phosphorus, sometimes more. Increasing crop yields, sandy soils, and leaching caused by high rainfall or irrigation are factors that influence the use of magnesium and sulfur in fertilizers. The use of fertilizer calcium strictly as a nutrient is limited and dictated by special crop needs and unusual soil conditions. Common fertilizer materials containing these secondary nutrients are potassium sulfate, sulfate of potash-magnesia, gypsum, normal superphosphate, magnesium sulfate, elemental sulfur, and calcium nitrate.

Calcium

Calcium is important not only as a plant nutrient, but also as a factor responsible for maintaining desired physical and biological conditions in the soil. Of the exchangeable bases found in soil (potassium, magnesium, calcium, and sodium), calcium is dominant, normally accounting for 50% to 80% of the total. Calcium is absorbed by plants as the Ca^{2+} ion. Inside the plant, calcium forms structural compounds that are part of cell walls, stimulates root and leaf development, helps activate several plant enzyme systems, and helps balance organic acids in the plant. Calcium is also important in the reduction of nitrates during the formation of plant proteins. Deficiencies in calcium manifest in abnormal development of growing points (terminal buds) and poor root growth.

Most soils contain sufficient calcium for plant growth. Many soils are too acid for optimum plant growth, however, before calcium application. Soil pH can be increased to a desirable level most economically with broadcast applications of finely ground agricultural liming materials. Lime supplies are virtually unlimited and commercial deposits have been found in most agricultural areas. Common lime materials are derived from calcite (CaCO_3), dolomite ($\text{CaCO}_3 \cdot \text{MgCO}_3$), and to a lesser extent, basic slag, which is a calcium silicate material that contains some phosphorus and magnesium. These materials are sometimes used as fillers in mixed fertilizers, although more than 95% of agricultural lime is applied

Table 6. Use of agricultural liming materials in the United States

Year*	Liming Materials, Mt

directly to soils. Table 6 shows agricultural lime consumption in the United States.

Soils of the humid regions east of the Mississippi River generally require higher rates and more frequent applications of lime. Soil calcium and magnesium may be leached from those soils by relatively high rainfall, resulting in a decrease in the soil pH. In addition, application of nitrogen fertilizers indirectly increases soil acidity. As a general rule, 3 kg/ha of calcite are required to neutralize the soil acidity resulting from every kilogram per hectare of nitrogen applied to soils. Typical amounts of calcium in the soil range from less than 0.1% to as much as 25%, with arid, calcareous soils containing the highest levels.

In addition to creating a desirable soil pH level for optimum plant growth and resulting in a more desirable soil physical condition, a secondary effect of lime is that soil pH influences the availability of other nutrients. Although phosphorus availability is greatest at pH 6.0 to 7.2, the micronutrients copper, iron, manganese, and zinc generally are less available as the soil pH approaches neutrality. These micronutrients must often be applied to the soil or crop as fertilizers.

Crops such as peanuts and tomatoes require a relatively large amount of soluble calcium. Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is often used where these crops are grown and is usually applied directly to soil rather than as a component of mixed fertilizers. Sources of much less significance for their calcium content are normal and concentrated superphosphates and calcium nitrate.

Magnesium

Magnesium is absorbed by plants as the Mg^{2+} ion. Its role as the central atom of the chlorophyll molecule is of major significance. Magnesium also aids in phosphate metabolism, plant respiration, and the activation of many enzyme systems. The use of high-calcium lime materials and the natural tendency of many soils to be low in available magnesium have stimulated the practice of including soluble magnesium sources in some premium fertilizer products. These soluble magnesium materials may increase the crop production efficiency of the primary nutrients.

Magnesium sources either added to other fertilizers or applied directly to soil can be classified by their chemical nature or by their degree of water solubility. A source must either be water soluble or convertible to a water-soluble form before the magnesium can be absorbed by the plant. Magnesium sources that are soluble or readily available are hydrated magnesium sulfates and sulfate of potash-magnesia (langbeinite: $\text{K}_2\text{SO}_4 \cdot 2\text{MgSO}_4$). Included in the hydrated magnesium sulfate group are kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$) and epsomite ($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$). Sources that are only slightly water soluble but that become soluble over a period of 2 to 4 years include dolomite, brucite ($\text{MgO} \cdot \text{H}_2\text{O}$), magnesite (MgCO_3), basic slag (which contains various nutrients and usually from 2% to 8% Mg), and periclase (MgO). Although most of the soluble magnesium materials are mixed with other fertilizers, nearly all other magnesium sources are directly applied to soils. Dolomite, by far the most significant source, is applied to soils at rates of 1 to 3 t/ha.

Sulfur

Sulfur has been recognized as an essential plant nutrient for more than 140 years. Further, it has been basic to the fertilizer industry since its inception because of the treatment of phosphate rock with sulfuric acid in the manufacture of superphosphate. In that process, the sulfuric acid reacts with calcium in phosphate rock, resulting in the formation of gypsum. Gypsum is not removed from normal superphosphate so that the product contains 1.2% sulfur. At one time, normal superphosphate was the chief source of sulfur in fertilizers, and nearly all mixed fertilizers contained some normal superphosphate. In recent years, however, increasing importance has been placed on high-analysis phosphates (the industry uses "high analysis" to mean "high nutrient content"). In these products, sulfuric acid is used to treat phosphate rock, but the sulfur is removed with further processing to higher analysis phosphate materials.

Some plants require almost as much sulfur as the yodophorus. Sulfur enters the plants as the sulfate (SO_4^{2-}) ion and becomes a necessary component of protein. It is also a constituent of the mustard oil glycoside, which imparts characteristic odors and flavors to such species as mustard, onions, and garlic.

The major sources of sulfur in today's fertilizers are ammonium sulfate, normal superphosphate, potassium sulfate, langbeinite, and gypsum. In chemically manufactured mixed fertilizers, sulfuric acid is still in wide use for neutralization of the ammonia used in their formulation. In certain areas where response to sulfur is obtained, langbeinite is increasing in importance as a sulfur source. Elemental sulfur also is commonly used, but its oxidation to the available sulfate form requires time and reduces soil pH levels.

Ammonium thiosulfate [$(\text{NH}_4)_2\text{S}_2\text{O}_3$] is a widely used sulfur source in the fluid fertilizer industry. It is made by reacting sulfur dioxide (SO_2) and aqueous ammonia, with further reaction with elemental sulfur. It contains about 26% sulfur, which soon oxidizes in soil to the sulfate form and is completely soluble in liquid N-P-K mixtures. It is important to the fluid fertilizer industry because fluids are normally sulfur-free and are not compatible with most other sulfur sources.

MICRONUTRIENTS IN FERTILIZERS

Micronutrients are essential to plants but are required only in minute quantities. The availability of specific micronutrients is related to soil pH, generally decreasing as soil pH increases from 5 to 7. Micronutrients that must be added to certain soils as fertilizers include boron, copper, iron, manganese, molybdenum, and zinc. Chloride has also been recognized as a micronutrient and has recently been noted to play an important nutritional role in small grains, corn, and sorghum. Micronutrient products may be divided into three primary classes: inorganics, organic complexes, and synthetic chelates.

In certain crops, deficiencies of micronutrients have been increasing in recent years. This can be caused by increased crop production, high yield goals, exclusive use of N-P-K fertilizers without micronutrients, and diminished soil reserves of available micronutrients. These factors have combined to increase the consumption of micronutrient fertilizers, particularly in recent years. Data on U.S. micronutrient consumption was not collected until 1967 when the U.S. Department of Agriculture obtained information from known producers of copper, iron, manganese, molybdenum, and zinc. Use of manganese and zinc is much higher than that of the other micronutrients. This is because manganese and zinc are mainly applied to corn, wheat, soybean, cotton, and rice, crops that are grown over the largest acreage in the United States.

Micronutrient sources vary considerably in physical state, chemical reactivity, cost, and availability to plants. They are classified as inorganic, synthetic chelates, and natural organic complexes. Typically micronutrient application rates are determined by correlating soil tests with levels found in plant materials. Plant analysis can also be used to confirm deficiencies, and amendments must be applied as early as possible, preferably before planting.

Micronutrient fertilizers, like primary nutrients, should be applied on an as-needed basis and are typically applied with multi-nutrient-mixed fertilizers. They may be incorporated in chemically manufactured fertilizers, in blends, or in fluids. In certain cases, micronutrients are applied directly to soils or used as foliar sprays. Micronutrients must be water soluble before they can be absorbed by plants. The solubility or availability of copper, iron, manganese, and zinc to plants decreases with increasing soil pH; that of boron and molybdenum generally increases with increasing soil pH. Ultimately, the choice of micronutrient source is related to the method of application, compatibility with other fertilizers, cost, agronomic effectiveness, and ease of application.

Boron

Boron is added to more fertilizers than any of the other micronutrients. Boron fertilizers usually are required for optimum growth of alfalfa, cotton, and clovers. A large number of plant species will not tolerate more than traces of soluble boron. Conversely, many plant species will not produce seed without adequate boron, and deficiency symptoms include stunting; hollow stems and fruit; discolored, brittle leaves; and poor pollination resulting in loss of flowers and buds. Boron is added to mixed fertilizers, typically as borate

ion (BO_3^-) or boric acid (H_3BO_3). Most plant-available boron is found in the soil or organic matter. Conditions that favor increased mineralization include warm, moist soil and good aeration.

Chloride

The chloride ion is the micronutrient most recently recognized as essential. Recent evidence indicates that chloride has a nutritional role in grains, corn, and grain sorghum. Chloride is very prevalent in soil, commonly occurring as soluble salts such as sodium chloride (NaCl), calcium chloride (CaCl_2), and magnesium chloride (MgCl_2). Chloride acts as the counterpoint during potassium uptake, thus playing a role in ionic balance, electrical charge balance in physiological functions, and the initial reactions of photosynthesis. Chloride deficiency typically presents with leaf tip wilt, with subsequent bronze discoloration followed by necrosis. Smaller kernel size, delayed maturity, and restricted, highly branched root systems may also be symptoms. Forms of fertilizer chloride can include ammonium chloride (NH_4Cl), calcium chloride, magnesium chloride, and potassium chloride. Each of these forms provides the additional benefit of nutrients, with ammonium chloride recently growing in popularity in the Midwest.

Copper

Copper is necessary for carbohydrate and nitrogen metabolism as well for lignin synthesis in cell walls. These structural properties help prevent wilting in growing plants. Copper is known to stimulate seed production and functions as a coenzyme and regulator responsible for photosynthesis and chlorophyll production. Because plants absorb copper readily, its application with mixed fertilizers is one of the important ways of ensuring that this essential nutrient in animal nutrition is in sufficient concentrations in animal feeds. Many soils—especially the leached, sandy, and excessively cropped soils—need copper applications for optimum crop production, and highly organic soils are also often deficient in copper. Copper is usually added to mixed fertilizers as sulfates, oxides, and chelates. Cupric chloride ($\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$), cupric oxide (CuO), copper sulfate monohydrate ($\text{CuSO}_4 \cdot \text{H}_2\text{O}$), and cuprous oxide (Cu_2O) are the some important sources from which copper fertilizers originate.

Iron

Iron is involved in chlorophyll formation and acts as a catalyst in plant growth. Lack of sufficient iron in plants results in a readily identifiable Fe-chlorosis or yellowing of the plant. Iron also functions within enzyme systems associated with energy transfer, nitrogen reduction and fixation, and lignin formation. Although most soils contain sufficient iron, it may not be available to the plant, particularly in calcareous, high-pH soils. Therefore, supplemental iron is applied as a fertilizer or foliar spray. Soil applications of inorganic iron sources generally are not effective in supplying iron for crops growing on high-pH soils. Inorganic sources such as ferrous sulfate (FeSO_4) or ferric sulfate [$\text{Fe}_2(\text{SO}_4)_3$] may be used as foliar sprays, but they are rapidly converted to forms that are not as available to plants when they are applied to soils alone or with other fertilizers. Some iron chelates are more effective for soil application, but their high cost restricts their use to crops with high cash values.

Manganese

Manganese is another essential micronutrient closely associated with iron and has somewhat similar functions in the plant. Manganese will not take the place of iron, but its absence or excess reduces the effectiveness of iron. Manganese, copper, and iron are probably the main oxidation-reduction regulators in plants. A avail-

able manganese is often deficient in agricultural soils, particularly those that have been recently limed. Manganese is supplied in the form of sulfates, oxides, oxysulfates, and chelates. Usually the less-soluble oxides are less effective, although this depends mainly on granule size. The primary forms that supply these manganese materials for fertilizer are manganese sulfate (MnSO_4) and psilomelane (mixed Mn-oxides), but the manganese in these sources must be reduced to the divalent form to be available to plants. By-product manganous oxide (MnO) is also used as a source of manganese.

Molybdenum

Of all the essential elements, molybdenum is required by plants in the lowest amounts. Molybdenum is present within the coenzymes that facilitate nitrogenase, an enzyme associated with the reduction of nitrates in plants. There are some soils on which little plant growth can be sustained without molybdenum applications. Molybdenum very often stimulates the growth of legumes because of its role in nitrogen metabolism. Given its role in pollen development, molybdenum deficiency may impair nitrogen metabolism, protein synthesis, sulfur metabolism, and grain and fruit formation. Notably, excess dietary molybdenum has been found to result in copper deficiency in grazing animals such as ruminants. The mechanism is the formation of thiomolybdates, which contain sulfur and molybdenum and appear to prevent the absorption of copper.

Molybdenum has a narrow “window” from essentiality to toxicity, wherein small excess amounts may cause harm. Molybdenum is incorporated, alone or as part of a general micronutrient mixture, in many mixed fertilizers in very low concentrations. Molybdenum occurs within soil minerals as an anion (MoO_4^{2-}), and is extremely mobile in soil. The main molybdenum sources are sodium molybdate and ammonium molybdate, which are produced from roasting of the mineral molybdenite (MoS_2), as is molybdic acid (Mo_3O_8).

Zinc

Zinc in plant nutrition is closely associated with the role of copper, mainly as a coenzyme. Most zinc-deficient plants are stunted or grow improperly, and maturity is often delayed. Zinc deficiency occurs in wide areas of the United States, but zinc fertilizers are mainly applied to corn and rice. Zinc is usually incorporated in mixed fertilizers as sulfates, oxysulfates, oxides, and chelates. Most of these sources have been prepared from the mineral sphalerite (ZnS) or from by-product oxides and sulfates from zinc-processing operations and other industries. Zinc, like copper, has a significant residual effect after application, lasting 5 years or longer. Soil testing is the most appropriate way to determine zinc levels.

REGULATION

Fertilizers are regulated primarily at the state level. The Association of American Plant Food Control Officials (AAPFCO) is an organization of fertilizer control officials from each state in the United States, Canada, and Puerto Rico who are actively engaged in the administration of fertilizer laws and regulations. Other AAPFCO members are research workers employed by these governments who are engaged in any investigation of mixed fertilizers, fertilizer materials, their effect, and/or their component parts. The organization strives to gain uniformity by consensus among each of these entities without compromising the needs of the consumers, protection of the environment, or fair competition among the industry.

ADVANCED EFFICIENCY FERTILIZER PRODUCTS

Fertilizer consumers today have many more viable nutrient management choices than they did just 10 years ago. Thanks to

advancements in technology, fertilizer consumers now have several options, including slow and controlled-release fertilizers and urease and nitrification inhibitors—which delay nitrogen availability—when deciding how to supply crops with the essential nutrients. Although controlled-release fertilizers have been around for more than 50 years, recent advances in technology have made them a cost-effective and viable alternative for row crops such as corn and wheat. Nutrient management plans to help increase efficiency and minimize unwanted environmental effects are becoming a requisite component of production agriculture. The use of advanced fertilizers can contribute significantly to protecting the environment by reducing nitrogen losses and improving nitrogen efficiency while improving yields.

Simply stated, slow and controlled-release fertilizers are either absorbed, coated, occluded, or reacted. All four types deliver extended, consistent supplies of nitrogen to the crop. Urease and nitrification inhibitors reduce the rate of transformation of nitrogen into a plant-available form.

Slow and Controlled-Release Fertilizer

These types of fertilizers contain a plant nutrient in a form that delays its availability for plant uptake and use after application, or that extends its availability to the plant significantly longer than a reference “rapidly available nutrient fertilizer” (such as ammonium nitrate or urea, ammonium phosphate, or potassium chloride). A variety of mechanisms can bring about such delay of initial availability or extended time of continued availability, including controlled water solubility of the material (by semipermeable coating, occlusion, or by inherent water insolubility of polymers, natural nitrogenous organics, protein materials, or other chemical forms); slow hydrolysis of water-soluble, low-molecular-weight compounds; or other unknown means. For instance, nitrification inhibitors inhibit the biological oxidation of ammoniacal nitrogen to nitrate nitrogen, whereas urease inhibitors inhibit hydrolytic action on urea by the urease enzyme. When applied to soils, the effect of these inhibitors is less nitrogen lost by volatilization. Of course, producers must recognize an economic or environmental benefit for these products to begin to gain widespread acceptance in the marketplace.

How Do These Products Work?

Advanced efficiency products may work in a variety of ways:

- As nitrogen sources with low solubility in wastewater resulting from a complex molecular structure that releases nitrogen through microbial decomposition
- As materials releasing nutrients through a coated surface
- As materials releasing nutrients through a membrane that may or may not itself be soluble (encapsulation)
- As nutrient-releasing materials incorporated into a matrix that itself may be coated
- As materials releasing nutrients in delayed form because of a small surface-to-volume ratio
- As absorbed fertilizers taken into an absorbent material in which availability of nutrients is increased through occlusion

Slow and controlled-release fertilizer and nitrification and urease inhibitors can increase the efficiency of nutrients applied, generally resulting in higher crop yields, while working to reduce nitrogen transport to air and water. Other advantages of these products include

- Improved agronomic efficiency
- Realization of significant savings in labor, time, and energy

- Lowered risk of environmental pollution by reducing the potential loss of nutrients to air and water between applications
- Uptakes by the plants through gradual nutrient release, increased nitrogen efficiencies, reduced emissions of nitrous oxide (N₂O), oxides of nitrogen (NO_x), and ammonia
- Increased mobilization of phosphate in the rizosphere
- Reduction of seedling damage when seed-placed levels of urea/urea-containing fertilizers are too high

In addition to ensuring that the soil is provided with sufficient nutrients to grow an abundant supply of food, the fertilizer industry is committed to the environmentally sound use of its products. Modern farming practices use fertilizer nutrients to build high-yielding, nutritious crops and also make it possible for people to continue to use large areas of land for forests, parks, and wildlife areas. Although available cropland continues to decrease (Figure 1), crop production continues upward.

The development of advanced fertilizer technologies has added an important facet to the fertilizer industry's environmental stewardship program and to the suite of BMPs farmers may utilize to keep nutrients “in the agricultural box.” With the use of these crop nutrients, farmers improve nitrogen efficiency by reducing excess nitrogen release and evaporation losses, thereby contributing to environmental protection. And because advanced fertilizer technology products are typically applied once per growing season, their use also reduces the potential loss of nutrients between applications and increases uptakes by the plants through gradual nutrient release.

ACKNOWLEDGMENT

The authors acknowledge the previous authors of this chapter, who provided a strong foundation, and Ford West, senior vice president, and Kraig R. Naasz, president, of The Fertilizer Institute, for having the insight to allow the authors to take on this task.

Adhesives, Caulks, and Sealants

Randy Sandrik

INTRODUCTION

Adhesives, caulks, and sealants (ACS) are compounds that bond or fill surfaces. Although they have different functions, these three categories are generally discussed together because they have similar compositions. Many ACS compounds include industrial minerals in their formulation with a loading, by volume, that ranges from 0% to 80% (average of roughly 50%). In practice, several hundred separate ACS compounds are used in thousands of different products.

Functionally, adhesives are chemical compounds that bond two surfaces together; they are used in packaging, construction, product manufacturing, and installation of wood, metal, rubber, plastics, ceramics, and fiberglass materials. Caulks are generally a low-performance sealant, thick and nonpourable with high concentrations of fillers. They are used to fill joints, spaces, or gaps. Higher performance sealants are based on polymers of sulfides, silicones, and urethanes and are used in weatherproofing, filling, sealing, and product manufacturing.

ACS is a global industry, and ACS sales in 2003 were about \$27 billion (Owen 2003). By region, this breaks down to \$10 billion in North America, \$8 billion in Western Europe, \$7 billion in Asia, and \$2 billion in the rest of the world. In the United States, this \$8 billion business employs 22,000 people, producing ACS in almost every state. Most ACS products are made in California, Ohio, and Texas (U.S. Department of Commerce 2004).

USES OF ACS

ACS compounds are used in almost every aspect of daily life, with myriad structural and nonstructural applications. The following is a breakdown of ACS use by industry:

- Construction: New building construction; fire stops; plaza decks; heating, ventilating, and air conditioning; bridge and deck joints; industrial assembly processes; renovation and finishing of homes; industrial assembly processes; ceramics; cladding; concrete; glass; fixed glass curtain walls; flooring; paneling; precast cement; roofing; structural glazing; and tiles.
- Automotive and aircraft sealants: Acoustics, gaskets and seals, joints and fasteners, interior sealants, threshold sealing, and window sealing.
- Equipment components: Aerospace applications, automotive components, glass, fiber-optic assembly, plastics, and surface-mount printed circuit boards.

- Packaging and labeling: Bags, hot and cold seals, wood gluing, and pressure-sensitive adhesives.
- Other industries: Carpeting, footwear, appliances, wire/cable, porosity sealing, glass fiber bonding, rubber, laminating, aerosol adhesives, medical (from bandages to cardiac surgery), marine, backing, and foam.

Table 1 lists some specific ACS products by classification as adhesive, caulk, or sealant.

FORMULATING ACS PRODUCTS

The formulation of an ACS product is based on economics and desired product properties. Industrial minerals, when included in the formula, tend to be used as extenders, fillers, or pigments. Although industrial minerals usually make up about 50% of the weight or volume of a typical ACS product, they represent only about 10% of the finished product costs. The more expensive basic components include the binder that provides the strength and adhesion required (normally organic resins), diluents (for viscosity control), hardeners (also known as curing agents that combine with the binder), catalysts, accelerators, inhibitors and retarders (to improve cure time), modifiers (which include the industrial mineral as a filler, extender, or pigment), thinners, plasticizers, stabilizers, and wetting agents.

Table 1. Specific products by classification

Adhesives		
• Tape	• Furniture	• Fiber optics
• Book binding	• Canvas treatment	• Factory housing
• Gaskets	• Synthetic fiber binding	
Caulks		
• Epoxy sticks	• Tub and tile caulk	• Caulking compound
• Drywall	• Adhesive caulk	• Plastering mud
• Putty tape	• Urethane caulk	
Sealants		
• Joint sealer	• Silicone rubber	• Polyurethane foams
• Room-temperature vulcanizing (RTV) silicone	• Waterproofing	• Bandages
	• Acoustical sealant	• Glazing

There are many ways to produce ACS but generally, four manufacturing systems are employed: (1) water base, (2) hot melt, (3) solvent, and (4) other. In the United States in 2003, the ACS manufacturing systems were water base (56%), hot melt (20%), solvent (14%), and other (10%).

CLASSIFYING ACS PRODUCTS

ACS products are classified in many ways, including by product type, by testing and standards, and by manufacturer type and subtype. Product types can be classified according to each product's method of bonding, bonding temperature, composition of the main components, number of components, form (elastic or rigid; structural or nonstructural), permanence, performance and conductivity, and application (water- or solvent-based).

Products are also described by performance testing that may include tensile strength, compression load, shear strength, peel load, plowing, torsional fatigue, and cleave load. Standards for ACS products include tear resistance, outgassing, durability, printability, mildew resistance, thermal performance, fire rating, acoustics performance, corrosion resistance, and atmospheric effects.

Manufacturers produce ACS according to the following end uses:

- Adhesives based on natural polymers
- Polymer dispersions and emulsions
- Hot-melt adhesives
- Solvent-based adhesive systems
- Adhesives—reactive (polymerizing) systems
- Adhesives based on water-soluble polymers
- Other adhesives
- Construction sealants
- Transportation sealants
- Consumer sealants
- Assembly/other sealants

For adhesives, manufacturer subtypes include assembly, building construction, consumer, footwear, leather, transportation, paper, and woodwork. For caulks and sealants, the subtypes are butyl, latex, modified silicones, oil-based caulks, polyvinyl acetate caulks, polysulfides, silicones, solvent acrylics, and urethane.

Adhesives can also be classified according to distribution channel (direct or via distributor to the end user); technology (hardening/nonhardening, hot/warm melt, solvent, or waterborne); and chemistry (acrylic, bituminous, epoxy, ethyl vinyl acetate [EVA], polyurethane, polysulfide, or rubber).

INDUSTRIAL MINERALS USED IN ACS PRODUCTS

Most ACS products contain industrial minerals, but not all (e.g., several hot-melt and polymer adhesives). Where industrial minerals are used, they are normally added as a single ingredient, but some blends are used as well. Globally, about 250 listed companies, with at least 1,000 operations, produce the following industrial minerals:

- Calcium carbonate as precipitated calcium carbonate (PCC) or ground limestone, marble, or chalk. These minerals are used to lower costs, and in some cases they may adversely affect ACS performance. PCC is also used in viscosity and rheology control and in high-performance adhesives.
- Clay as kaolin, attapulgite, or bentonite. These are used to lower costs and improve performance, with air-floated kaolin improving flow properties and water-washed kaolin raising viscosity to allow for water addition. Calcined kaolin is used in automotive glazing systems. Surface-treated kaolin is also used (alkyl or vinyl silanes) for higher-performance ACS.

- Other industrial minerals, added for very specific reasons, including color, are used in lesser and varying quantities:

- Silica, as precipitated or fumed
- Tripoli
- ATH (aluminum trihydrate)
- Feldspar
- Barite
- Aluminum hydroxide
- Mica
- Talc
- Wollastonite
- Titanium dioxide, TiO₂
- Antimony oxide
- Gypsum
- Pulverized waste

When producing an ultrafine or specialty ACS product, the filler would include the following specialty products, which are also produced globally by many companies.

- Nano-calc and nano-clay
- Fused silica
- Carbon black
- TiO₂

The industrial mineral loadings in ACS typically are adhesives, 0% to 60%; caulks and putty, up to 85%; and sealants, 0% to 40%.

Production and Consumption of ACS

In 2003, 10 Mt of ACS products were produced, at an average cost of \$1.34/lb. This ACS production consumed about 5 Mt of industrial minerals for fillers, extenders, and pigments (Owen 2003). In the same year, global use of 5 Mt included 3.7 Mt of calcium carbonate, 0.7 Mt of kaolin, and about 0.6 Mt of other industrial mineral fillers. Combined, these have a total value of approximately \$300 million.

Because of its low cost and consistent properties, calcium carbonate is the most widely used filler, extender, and pigment in ACS, at about 3.7 Mt in 2003. Coarse, medium, and fine products are used, and prices in the United States in 2003 ranged from \$24/t to \$140/t, averaging \$50/t. In 2003, the global amount of air-floated and water-washed kaolin, the usual forms of kaolin used in ACS was estimated at 0.7 Mt. Kaolin costs are much higher than ground calcium carbonate (GCC) and are generally more than \$85/t. Other mineral fillers, including some grades of PCC and nano-grades, are more than \$250/t.

MARKET OVERVIEW

Market Environment

ACS producers include large national sealant, caulk, and joint compound suppliers and specialty adhesive suppliers. They are regionally supplied, but follow global manufacturing processes.

Industrial minerals suppliers are normally large commodity producers that have the capacity needed to supply large ACS plants. Their processes are geared toward consistency of color and particle-size distribution.

ACS Market Dynamics

Historical market drivers have included new commercial and residential construction and remodeling of homes and commercial properties. Future drivers will include environmental requirements, and growing uses in automotive, electronics, and medical equipment markets.

A few multinational players who have R&D capabilities, brand recognition, and raw material buying power dominate production of ACS. The top 10 producers of ACS in the world in 2003 were Henkel/Locktite, H.B. Fuller, National Starch, Bostik Findley, 3M, Sovereign, F orbo, Rohm and Haas, Berwind (Elmer's), and GE Silicones. In the United States, these producers, as well as USG, Georgia Pacific, National Gypsum, DAP, KCG, Red Devil, and Dow, sell both to "Big Box" retailers who have large buying power and to contractors and distributors, where some brand loyalty still exists.

ACS producers are high-volume/low-price buyers of industrial minerals. Although they look for unique specifications, they also seek to commodify all raw materials. They often bid business out and use multiple suppliers to guarantee supply and keep prices low. They are regional so as to minimize their delivered costs, but their products must meet global specifications. Table 2 lists the attributes and characteristics on which ACS producers and their customers focus.

COST COMPONENTS OF ACS IN THE UNITED STATES

As a reference to relative cost, the following summarizes data from the U.S. Economics and Statistics Administration (U.S. Department of Commerce 2004) on the percentage of cost of raw material components of an average ACS product:

• Other industrial organic chemicals	23%
• Manufacturing parts and supplies	16%
• Resins	14%
• Industrial inorganic chemicals	12%
• Industrial minerals fillers and extenders	10%
• Refined petroleum products	8%
• Synthetic rubber	6%
• Paper and cardboard containers	6%
• Plastic containers	4%
• Starch/dextrin	1%

INDUSTRIAL MINERALS USAGE

The primary industrial mineral used is dry GCC. ACS producers use dry-process GCC for three reasons:

1. Cost reduction (although high GCC loadings adversely affect some performance characteristics). The use of GCC will normally lower binder requirements and allow for increased filler usage.
2. Shrinkage control, improved rheological properties, and water resistance.
3. To provide body and provide optimum adhesion within joints.

MARKET TRENDS

Global demand for ACS was forecasted to increase by 2% to 4% per year from 2002 through 2012. In the United States, the increase was forecasted at 3.5% per year from 2002 to 2012. This forecast included a recovery from the 2001 recessionary base, normal growth, and the introduction of new markets and improved ACS products.

For the same time period, adhesive growth in China is forecast at a 9% annual rate, with many end uses advancing at a double-digit pace. Production of ACS in China has been reported as one of the fastest developing sectors of the country's chemical industry. This is driven by an acceleration of new products, new technologies, and new application areas; some of the growth is from lost production from other countries (as more value-added products are being manufactured in China). Shipments are increasing for both the domestic and the export markets. Problems being addressed in China include decentralized production (more than 1,800 separate plants), lack of

Table 2. Focus of ACS producers and customers

Attribute	Characteristic
Safe	Components of degradation products pose no dangers.
Effective	High loading and adhesion strength.
Usable	Ready to apply; remains manipulative for a short time; solidifies rather quickly.
Affordable	Cost per unit is not prohibitive.
Approvable	No issues with Food and Drug Administration and other agencies

R&D (materials urgently demanded by the market are not being delivered), and insufficient raw and auxiliary materials (primarily resins and solvents that need to be imported) (Yang 2002).

Global ACS growth is driven by increased construction demand (1% to 3%) and increased growth (1% to 3%) from a new demand structure that includes electronics, medical, mechanical fastener replacement, automotive, and solvent-free products. Growth will also continue in higher performance ACS, such as silicones, polyurethanes, and urethane acrylic formulations. The use of PCC, nano-calc, and nano-clays will also influence future product mix. Influential co-products include polyvinyl acetate/acrylic resin and epoxy resin.

Finally, emerging regions of the world (with a combined population of nearly 4 billion and a total gross domestic product of \$7 trillion in 2003) are likely to see the largest growth rate in ACS consumption. By example, their adhesive consumption per capita in 2003 was less than \$2, well below the more than \$20-per-person consumption in the United States. Growth in the emerging economies can be uneven, but in the long term, ACS growth is projected to outpace the overall global economy.

SALES AND DISTRIBUTION DYNAMICS

Logistics drives the use of raw materials for both ACS and the industrial minerals used in ACS. The ACS industry has thousands of small plants, most tied to nearby raw material suppliers and many near population (use) centers. Most ACS plants are small volume and market located. The industrial minerals used by the ACS product formulators tend to be local. Future opportunities include joint efforts, formal or informal, in logistic areas such as reusable pallets, shared plant locations, hauling contracts, and ties into the ordering pattern of downstream ACS users.

Many goods that require ACS, including stand-alone ACS products, rely on distribution systems to get products to diverse and fragmented users. This distribution system has changed significantly over the last 20 years and will continue to evolve. Marketing costs can be up to 30% of sales, and distribution costs can be 15% of sales.

Current considerations include

- Electronic data interchange (EDI) ordering
- Just-in-time-type rapid filling of shipments
- Contractual pricing
- Drop shipments of less-than-truckload quantities to individual stores
- Placement fees, slotting allowances, store detailing, and special terms

PRODUCTS SPECIFICS

Raw Materials

The primary industrial minerals used are calcium carbonate and kaolin.

About 100 large companies and dozens of smaller operations worldwide own calcium carbonate and kaolin raw material supplies. Their mining and processing methods are simple, reserves for expansion exist, entry costs are not prohibitive, permitting is relatively easy because they tend to be seen as “green” compared to other mining, the royalty rates are low, and the operational structure allows for long-term and consistent production.

Dozens of registered companies supply almost all of the other industrial minerals’ content used globally.

Mining and Processing

Surface truck/shovel mines or simple room-and-pillar underground mines produce calcium carbonate for ACS. The mining cost is about one fourth of the total free on board (f.o.b.) raw material cost. Processing, which is about one half of the cost, includes washing or scalping (at some locations), and crushing and grinding. Packaging, which is about one fourth of the cost, is simple, with bulk, semi-bulk, and bagged packaging all easily available. Transportation of finished goods, at about \$0.10/ton-mile in most of the world, can represent 1, 2, or 3 times the actual cost of the industrial mineral f.o.b. purchased price.

Almost all kaolin for ACS is surface mined using conventional dragline or truck/shovel operations. Including reclamation and restoration, the mining cost is also about one fourth of the f.o.b. cost. Processing includes blunging, degritting, and other required application and decontamination steps. With few kaolin operations globally, overall transportation costs are usually high.

PRODUCING ACS

Of the total ACS volume produced, more than 50% is normally made in simple blending/mixing facilities where small batches are mixed, aged, and placed into buckets and boxes that are filled and shipped in case lots. Although the manufacture of adhesives and sealants involves relatively simple processes, extensive knowledge and experience with the raw materials and their formulation and compounding are essential. Few companies perform R&D in these areas. A few of the larger adhesive and sealant manufacturers are vertically integrated, producing resins for captive consumption. Other firms in the industry are highly dependent on raw material suppliers for introducing new technologies. The adhesive and sealant companies then assume responsibility for formulating these new raw materials into products that offer improved performance. This aspect of formulation is where most adhesive and sealant companies derive their competitive advantage—by designing and producing products to satisfy a particular market demand.

MARKET SPECIFICS

Finished Product Specifications

There are thousands of ACS products; therefore, this chapter cannot address individual specifications. The trend for ACS producers will include a base load of commodity grades made at as low a cost as possible, and a continued shift in product mix to higher performance sealants and caulks such as silicones, polyurethanes, and urethane acrylic formulations. High levels of consistency in ACS products are also required. ACS producers will increasingly compete on product performance, consistent thickness, short drying times, adhesion, shrinkage, and color.

Customer Demands

ACS producers see value in many of the following key areas:

- Loading levels (e.g., more industrial minerals loading is better, and loadings of up to 85% are reported)

- Cost reduction (e.g., the pressure is on producers to cut costs each year, and they are improving in their understanding of cost drivers and relationships—such as mean particle size and particle-size distribution—to energy cost. Producers are also beginning to practice state-of-the-art supply chain dynamics.)
- Waste minimization (e.g., using an aggressive data collection and management system, evaporating water from aqueous wastes, using just-in-time coloring, and using solvent recovery)
- Product consistency (e.g., most producers prefer consistent tint and brightness to minimize TiO₂ usage and swings in their products’ color)
- Delivery when expected (e.g., most producers practice just-in-time and other cash-cost-reduction techniques)
- Ability to supply (e.g., a large segment of the ACS business is seasonal, and industrial minerals suppliers must be able to seamlessly meet the changing producer’s demand)

GOVERNMENT, ENVIRONMENT, AND HEALTH CONSIDERATIONS

Environmental, health, and safety issues have been the driving force behind many recent technological changes in ACS production and products.

Volatile Organic Compounds

In the late 1980s, several world governments and nongovernmental organizations identified adhesives and sealants as significant sources of volatile organic compounds (VOCs). In combination with nitrogen oxides, VOCs are responsible for the buildup of ground-level ozone in populous regions of the world. This ozone causes respiratory problems, vegetation damage, and material degradation. Government, environmental, and health goals have often necessitated reformulation of ACS products. Shifting to water-based formulations can significantly reduce the use of petroleum solvents. In addition to reducing VOC emissions, water-based formulations offer advantages such as easier cleanup and less odor. One type of low-solvent formulation (the hot-melt products) is designed for application at elevated temperatures. Low-VOC ACS products are now more commonplace and improved than they were 5 years ago, but their use is restricted by higher costs and by contractors not trained in their differing properties.

Asbestos

Asbestos concerns swept through the industrial minerals portion of the ACS industry in the 1980s and 1990s. Of specific concern was locating asbestiform minerals in the fillers. After the amounts of asbestiform were found to be nonexistent to very low, these concerns faded.

Respirable Crystalline Silica

A current concern is respirable crystalline silica levels. Crystalline silica in the form of quartz is a component of many industrial minerals used in ACS. The manufacturers of ACS will be on the lookout for low-crystalline products and silica-conscious industrial minerals producers. Manufacturing facilities, including mixing rooms and dry product storage, may need to meet the same respirable dust requirements of facilities that have been mandated to handle lead, arsenic, and cadmium.

Renewable Materials

The use of renewable materials and renewable energy in the manufacture of ACS products and their constituents is increasingly important. Industrial mineral producers will want to stay abreast of ACS

producers' concerns as they consider formulations that contain lignins, tannins, carbohydrates (such as soybeans), terpenes, and proteins. The longevity and quality of ACS products, and their own use in making "green products" and helping conserve energy and other resources, will also be important marketing considerations.

TRENDS AND OPPORTUNITIES

ACS is a relatively low-cost component in engineered construction and consumer products. Demand for ACS in the United States is forecast to increase 3.5% per year to 2.5 billion pounds in 2006, while European demand will continue to be half that rate. Demand in China and Asia is likely to grow at even higher rates. The global market will benefit from a moderately favorable outlook in the key durable-goods sector; the ability to displace nails, screws, and other fasteners; increased desire for lightweight composites; and technology breakthroughs in product designs that improve heating and air-conditioning efficiency.

Specific Trends and Opportunities

ACS companies will boost R&D spending. They will increasingly partner with global industrial minerals producers, especially those that can offer both a bundle of minerals and global product consistency.

Some specific targeted improvements include new formulations, including using epoxies to improve adhesion qualities to meet or exceed those of nails, screws, rivets, and other fasteners and welding. A selective use of industrial mineral fillers for weight reduction will help lower delivered costs, and additional use of surface chemistry and surface area of industrial minerals will enhance thixotropy.

New combinations of industrial minerals will provide greater ACS stability and less solvent creep. This will be especially important as ACS users evaluate the ease of robotic applications.

Finally, more environmentally friendly products are being demanded, and the industrial minerals components are generally seen as "green." ACS producers seen as winners will be those who use more fillers and less problematic ingredients such as solvents—this will be key to global market share.

Construction Markets

Construction markets will remain dominant. Housing is growing all over the world, and ACS products are used in new construction, renovation, and finishing of homes and commercial buildings. In the motor vehicle market, also an important segment, sealant usage will get a boost from acceleration in passenger car production; design trends featuring more glass, plastic, and rubber per vehicle; weight reduction; and powder clearcoat commercialization. In structural glazing—a construction process in which caulks/sealants hold glass panels in high-rise buildings in place—silicone products can be used without any mechanical means of fastening. This can be clearly defined as an adhesive application since the silicone material is being used to bond the glass and metal surfaces together. On the other hand, it also serves as a caulk/sealant because it prevents the passage of gases, liquids, or solids through the joint.

Accelerated defense spending will provide opportunities for sealants and caulks in the manufacture of military equipment.

Demand for sealants and caulks in the industrial sector will benefit from a stronger capital-spending environment as companies invest more heavily in new plants and equipment. Although durable-goods markets will see the most rapid gains, the construction industry will remain the largest outlet for ACS, accounting for more than half of total demand by 2006. Though a slowdown is expected in new building construction activity, continuing architectural trends

toward more luxurious and energy-efficient homes will partially offset deceleration in the number of new homes built by raising per-unit consumption of sealants.

In addition, non-building-construction markets, which were quite weak for most of the 1990s, will be boosted by the Transportation Equity Act for the 21st Century, which authorized federal spending programs for highways, bridges, and mass transit projects through 2003. This piece of legislation, and similar infrastructure construction and renovation projects worldwide, should provide opportunities for sealants and caulks in the mid-term, primarily in applications such as sealing expansion and horizontal joints in bridges, parking garages, playgrounds, sidewalks, and aircraft terminals, and sealing cracks in pavement and asphalt.

RAW MATERIAL REQUIREMENTS

New Product Volumes Required

Following are estimates of new mineral production required (from 2003 to 2013) by major ACS industrial minerals components:

• Calcium carbonate	1.2 Mtpy
• Clay	0.2 Mtpy
• Pulverized waste	0.1 Mtpy
• Silica, as precipitated or fumed	<0.1 Mtpy
• ATH	<0.1 Mtpy
• Feldspar	<0.1 Mtpy
• Gypsum	<0.1 Mtpy
• All other industrial minerals	<0.1 Mtpy

Specifications

ACS producers historically used existing industrial minerals producers' grades, many times adjusting formulas to meet local production. Increasingly, the ACS producers are settling in on "best" specifications and are demanding that these specifications be met by a supplier, or suppliers, globally.

These specifications are getting more complicated. Described here are those guidelines, with consideration of a carbonate raw material:

- Mineral (calcium carbonate, magnesite, other)
- Mineral processing (coarse, fine, or ultrafine; PCC or nano-GCC; dry or wet ground; etc.)
- Mineral surface (shape, area, surface treatment, and surface chemistry)
- Size (particle-size distribution [coarse, fine, ultrafine, and nano]; also specifics such as top size)
- Color (amount of yellow, green, red)
- Brightness
- Chemistry (amount of calcium, iron, aluminum, other)

Besides specifications, the ACS producers, and their downstream users, are demanding new levels of consistency, and many producers must now also describe their products in terms of how the processes behave (are they in control, are they capable), and they must supply product CPK data.

SUMMARY AND CONCLUSIONS

The ACS industry is an important consumer of many industrial minerals and is dynamic, with a growth rate that is faster than the global economy. ACS producers are focused on cost reduction and product property improvement, and many producers believe that an increase in the percentages of industrial minerals in their products will result in lower costs and improved properties. To this end,

many ACS producers will continue to look for strategic partners and alliances with industrial minerals producers.

Filler and Coating Pigments for Papermakers

Ian Wilson

INTRODUCTION

Historians attribute the Egyptians in the Nile Delta with preparing the first type of paper, from a marsh grass called *Cyperus papyrus*. They cut the plant's stem into thin strips, softened them in the river, and then pounded them into thin sheets that were then left to dry in the sun. The resulting sheets were ideal for writing on, and Egyptians, Greeks, and Romans used them for record keeping, spiritual texts, and works of art. Papyrus is the basis of the word *paper*. The father of papermaking is Ts'ai Lun, who in 105 AD experimented with a wide variety of materials and refined the process of macerating the fiber of plants until each filament was completely separate. He mixed the individual fibers with water in a large vat with a screen that was submerged and then lifted up through the water, catching the fibers on its surface; when dried, this thin layer of intertwined fiber became what we today call paper. The art of papermaking spread to the Middle East and to Egypt, where it replaced papyrus in the 9th century, followed by Morocco and then Spain (about 1150) and France (1190).

Industrial minerals play a major part in the manufacture of modern paper. Originally, because they were less expensive than fiber, minerals such as calcium carbonate (chalk) and kaolin were used as fillers to reduce production costs. Although cost is still an important factor, minerals have become "functional fillers" that impart specific properties to paper, such as improved printability, brightness, opacity, and smoothness. In paper coating, minerals are used as white pigments to conceal the fiber, thereby improving brightness, whiteness, opacity, and smoothness.

PAPER INDUSTRY STRUCTURE

World Production

In 2003, world production of paper and paperboard was 339 Mt compared with 239 Mt in 1990. A split of this production for 2003 (Table 1) indicates similar levels from North America, Europe, and Asia. Between 1990 and 2003, North America's share of the world market fell from 37% to 30%, whereas Asia increased from 25% to 32% as both Western and Eastern Europe decreased from 33.7% to 31%. The world average annual growth in the production of paper and paperboard during the period from 1990 to 2002 was +2.8%, with Asia showing the largest growth of +5.2%. Of the 339 Mt (Table 1), Asia is now the leading producer with 32%, just overtaking North America and Europe with 30% and 31%, respectively. The top ten producing countries in the world now account for 73%

Table 1. Paper and paperboard production by region in 2003

Region	Production, kt	% of World Production (rounded up)
Asia	110,585	32
Europe	104,093	31
North America	100,280	30
Latin America	16,254	5
Australasia	3,871	1
Africa	3,672	1
Total	338,755	100

Adapted from Paperloop 2004.

of production (Paperloop 2004), led by the United States (24%), China (12%), Japan (9%), Canada (6%), Germany (6%), Finland (4%), Sweden (3%), South Korea (3%), France (3%), Italy (3%), and all other countries (27%).

The growth of the Chinese market from 1992 to 2003 was dramatic, especially when compared with Japan (Figure 1): the growth rate was 13.1% in China, and the rate decreased by 1.3% in Japan. The Chinese growth was mainly driven by major companies investing in new paper mills in China (including Asia Pulp and Paper Company [APP], UPM-Kymmene, Stora Enso, and Oji Paper) combined with the fast-growing, apparent consumption per capita—in 2003 paper consumption was 36 kg in China, an increase of 24% over 2002. This is still well below the levels of the United States with 301 kg, the United Kingdom with 207 kg, as well as many other countries; and just ahead of Indonesia and India with 23 kg and 6 kg, respectively.

Fibrous Plant Materials Used in Papermaking

Although almost any plant material can be used for papermaking, very few are used because a number of factors determine what makes a good raw material:

- The plant must be abundant, inexpensive, and, if a waste product, of little use to others. It must grow in an accessible place and should grow quickly.
- It must contain a high proportion of cellulose fibers, and its structure must allow the fibers to be isolated from the rest of the plant material with reasonable ease and without undue expenditure of chemicals or heat.

Adapted from Paperloop 2004.

Figure 1. Growth in paper market for China versus Japan, 1993 to 2003

- The fiber itself when isolated should be suitable for paper-making, which means that it should be long and strong, and develop strength on beating. At the same time, it should be capable of being bleached to a good color without undue loss of strength.

Of the many species of plants in the world, the following meet the above requirements and are commonly used in papermaking:

- Seed hairs—cotton
- Bast fibers—flax, hemp, jute, ramie
- Wood fibers—coniferous and deciduous woods
- Leaf fibers—esparto, manila, sisal
- Grasses—bamboo, bagasse

Potential new pulp sources are being developed all the time. Malaysia, for example, announced in March 2003 that the world's first oil-palm-based pulp plant would be set up in Sabah (Borneo) with the capacity to produce 25,000 t of pulp. A new pulping method using empty fruit bunches (EFBs), which are currently a waste product from the palm oil industry, will be developed using

caustic soda technology. If successful, Malaysia has the potential to produce 3 Mtpy of pulp from EFB alone.

Main Paper Grades

Table 2 summarizes the main types of paper grade, their fiber composition, pigment filler and coating loading, and their end uses. Coated paper is coated on one or both sides with a mix of clay and carbonates to create a high quality printing surface. Coated paper can be fine, light weight, medium weight, or machine finished. Uncoated fine paper is used principally for printing and writing. Woodfree, freesheet, or fine paper is paper used by the graphic industry for writing, including office paper such as photocopying and laser printing paper; these may be coated or uncoated.

Leading Producers of Paper and Paperboard

The paper industry continues to consolidate, with the top 10 companies accounting for an increasing proportion of world paper and board capacity. Production by the 10 leading companies in 2003 accounted for 27.9% of global output (Table 3).

In 2001, Finnish-owned Stora Enso increased its capacity to 15.1 Mtpy and International Paper closed down 2.2 Mtpy of its less-efficient capacity; in the same year, UPM-Kymmene acquired Haindl, a leading European producer of publication paper. Publication paper includes newsprint, coated, and uncoated papers (mainly lightweight coated [LWC] and SC). This further consolidation increased UPM-Kymmene's capacity from 8.285 Mtpy to 11.705 Mtpy by 2003. UPM-Kymmene is now the world's largest manufacturer of magazine paper (LWC and SC) with an annual capacity of 5.465 Mt, or about one-quarter of the global market for magazine paper.

MAJOR PIGMENTS USED IN PAPERMAKING

The major pigments used in printing and writing paper (P&W; includes SC, MFC, WFU, and WFC) are calcium carbonate (precipitated calcium carbonate [PCC] and ground calcium carbonate [GCC]), kaolin, and others (talc, TiO₂, and others). Harris (2004) estimated that 30 Mt of these major pigments were used worldwide

Table 2. Paper grades, fiber composition, pigment and coating loading, and end uses

Paper Grade	Fiber Raw Material	Pigments	End Uses
Newsprint	De-inked pulp and/or mechanical pulp	Filler loading up to 12%, originally from de-inked pulp	Newspapers, inserts, flyers (advertising)
Specialty newsprint Books, papers High brightness	De-inked pulp and/or mechanical pulp	Filler loading <10%; specialty pigments can be used as well	Newspaper supplements, newspapers, books, directories, advertising
Supercalendered (SC) papers SC B, A, and A+ grades	Mechanical and chemical pulp	Filler loading up to 35% Filler loading up to 10%; coating 25%–30% of paper weight	Multicolor magazines, catalogs, supplements, inserts, advertising materials; used in gravure and offset printing
Coated mechanical papers (also called machine-finished coated [MFC] paper)	Mechanical and chemical pulp	Filler loading up to 10%; coating typically from 20%–35% of paper weight	Magazines, catalogs, supplements, books, advertising materials
Woodfree uncoated (WFU) papers	Chemical pulp	Filler loading up to 25%	Office papers, writing papers, envelopes, direct mail, magazines, books, advanced materials
Woodfree coated (WFC) paper; also coated fine paper (art printing paper)	Chemical pulp, possible to use some chemi-thermomechanical pulping (CTMP)	Filler loading up to 15% and double/triple coating	Magazines, brochures, direct mail, annual reports, books, advertising materials; higher quality books, reports
Specialty papers	Chemical pulp	Filler load and coating dependent on grade	Label papers, label release papers, food wrapping, packaging
Kraft papers	Chemical pulp	No pigments	Sacks, bags, wrapping and packing, envelopes

in 2002 (Harris 2004), and Figure 2 shows the breakdown of use. Of the 30 Mt of pigment used, 18 Mt was for coating pigments and the split was GCC (53%), kaolin (35%), PCC (9%), and others (3%; this was mainly talc, titanium dioxide, and a few others). The remaining 12 Mt is used as a filler.

ROLE OF PIGMENT PROPERTIES IN PAPERMAKING

For the papermaker, the critical pigment properties are

- Physical properties (also includes optical properties such as brightness, yellowness, and shade; coverage; ink absorption; and others)
 - Particle size and shape
 - Particle-size distribution
 - Aspect ratio (platiness or blockiness—kaolin can be platy and blocky but calcium carbonate is generally rhombohedral [hexagonal] for marble [crystalline limestone])
- Pigment moisture (for pigment handling)
- Pigment hardness—abrasiveness (wear on wire, doctor and slitter wearing)
- Residues, impurities, contamination—origin can be from processing the industrial mineral, from transportation, and from other sources (“runnability”^{*} in paper machine or coating or calendering causes streaks and breaks, which are expensive)

ROLE OF FILLERS IN PAPER

Fillers are highly desirable in printing papers because they increase the opacity, raise the brightness, and generally improve printing properties. The main types of mineral filler for acid papers are talc, hydrous kaolin, calcined kaolin, precipitated silicas and silicates (PSS), and titanium dioxide. For neutral/alkaline papers, talc, hydrous kaolin, calcined kaolin, PSS, titanium dioxide, GCC, and PCC are used. The use of fillers is important when opacity is needed at a low-basis weight, and they are invaluable in packaging grades where low permeability is combined with opacity to protect food from light. There are many fillers: barite, GCC (based on chalk, limestone, and marble), PCC, kaolin, pyrophyllite, mica, gypsum, plastic pigment, satin white, alumina, and titanium dioxide. The properties of the filler derive from the ability of the filler particles to refract and backscatter light through the surface of the sheet. If the filler is not evenly dispersed through the sheet and flocculates in small clumps, then the optical efficiency of the filler will be reduced. If the z-direction distribution of the filler is uneven, then the sheet may appear two-sided. The whiteness of the filler relates to the dominant wavelength of the light. Excluding some uncoated book-publishing grades, papers tend to have a blue whiteness. This requires adding a blue or violet dye to shift the shade of the paper into the desired region of the spectrum.

Because dyes reduce brightness, high-brightness filler must be used or optical brightening agents added for premium grade, such as company stationery and direct mail papers. The importance of avoiding filler flocculation emphasizes the point that fillers are not simply inert optical entities but interact with other additives, not only in terms of their own distribution but also to influence sheet structure such as formation, bulk, pore structure, and surface topography (texture). Aside from their optical effects, fillers or filler blends can be used to improve aspects of product uniformity and

Figure 2. World pigment use in P&W paper (2002)

quality. An understanding of filler interactions with retentions aids, sizing agents, cationic starch, and the dynamics of the wet and forming systems is required (Jopson and Moore 2004).

The main driving force for filler in fine papers is to substitute more expensive fiber with filler. No filler is capable of producing maximum light scattering for brightness and opacity without having any detrimental impact on wet web strength and sheet physical properties. The best pigments for brightness and opacity debond fibers the most because of their inherent high surface area.

Kaolin, calcium carbonate (GCC and PCC), and talc are the most widely used mineral fillers, with regional variations depending on local resources available. Table 4 lists the pigments used as filler in different printing paper applications. In the United States, PCC is widely used as filler because of the wide availability of limestone; the lime produced from limestone is converted into PCC at a state lime plant adjacent to a paper mill. Filler pigments must have a high degree of whiteness, a high index of refraction, small particle size, low solubility in water, and low specific gravity. It is also important that the filler be chemically inert to avoid reactions with other components in the sheet and in the papermaking system. The filler should contain a minimum of impurities, and the grit content must be low to avoid excessive wear of the wire and other processing equipment such as cutting blades. Furthermore, unless the filler has very unusual properties, it must be inexpensive.

Hydrous Kaolin

Kaolin was the usual filler used in Europe and the United States up until the 1990s when the use of PCC in the United States and GCC

^{*} Newspapers and magazines require long runs on the printing presses, and several factors affect how well a paper will run on the press. Runnability describes a paper's ability to hold ink on its surface consistently and to absorb ink uniformly, along with its dimensional stability and its surface texture.

* Most of the ash comes from recycled fiber in newsprint, if the main raw material is recycled paper.

† A part of the ash comes from coated broke in coated paper.

in Europe emerged. The main use of kaolin fillers in the last decade has been in engineered products. The new range of filler content for SCA paper is based on the production of a high-aspect-ratio (often >40) filler and a controlled particle-size distribution of about 50 wt % <2 µm and a minimum of 5% >10 µm. These high-aspect-ratio kaolin products, with a brightness of ISO 82, provide good opacity to the base paper. They are particularly useful in SCA papers where the platy kaolin with calendering gives a sheet that can compete with LWC papers. The development of a range of platy kaolins has been at the expense of the less expensive kaolin filler.

Over the past two decades, additional processes have been developed to improve the quality of the kaolin from the deposits in Cornwall in the United Kingdom. These deposits have been well documented in the literature (Exley 1959, 1976; Sheppard 1977; Halliday 1980; Allman-Ward et al. 1982; Alderton and Rankin 1983; Bray and Spooner 1983; Allman-Ward et al. 1985; Bristow and Exley 1994; Bristow 1995; Manning, Hill, and Howe 1996; Scott, Hart, and Smith 1996; Psyrillos, Manning, and Burley 1998; Psyrillos et al. 1999; Bristow et al. 2000; Thurlow 2001; Bowditch, undated). For brightness enhancement, superconducting magnets have been introduced alongside high-intensity magnetic separators (HIMSs), froth flotation, selective flocculation, and selective separation processes to remove abrasive materials such as quartz and feldspar. The most significant processing development over the last decade, however, has been the production of delaminated clays from vermiform or stacky kaolinites so that approximately 60% of the processed Cornwall kaolin is now delaminated. The flow process at low-abrasion plants involves flotation to remove contaminants (feldspar, quartz, and mica) and a sand grinder (known as such because it once used a round resistant sand as the grinding medium; a ceramic bead is now the preferred medium) for delamination.

The aspect ratio of the resultant delaminated kaolin is an important parameter, and Imerys developed a stop-flow conductivity measurement instrument that gives a shape factor (called a factor because aspect ratio is not actually measured). The method is known as PAN-ACEA (particle assessment [by] natural alignment [and] conductivity effect analysis). Measurements of shape factor are made online and help to control the process. Historically, aspect ratio was measured using the transmission electron microscopy (TEM) platinum shadowing technique, which was a very lengthy process relying on the particle thickness being proportional to the shadow length—the thinner the platelet of kaolin, the narrower the shadow.

The base paper pigment has an important bearing on the subsequent coating pigment application. The influence of the base paper structure is more noticeable when the paper is coated with

GCC because its particles pack less efficiently on the surface compared to the platy and broad particle distribution kaolin (Bown 1991; Lorusso 2002; Hiorns and Nesbitt 2003). Although it is clear that coating color formulation and coating conditions have potentially greater influence on the coated paper quality, the filler content of the base paper has a profound effect on coating runnability and paper quality.

Calcined Kaolin

Calcined clay is used in small amounts in newsprint and as an addition to other fillers to replace more expensive titanium dioxide to improve opacity. With the onset of calcined clay as filler in newsprint, it is common now to have newspapers with color photographs not visible through the sheet because of its increased opacity.

Calcium Carbonate

The conversion from acid to alkaline papermaking techniques and the demand for brighter and bulkier paper have been the main drivers behind the increased preference for calcium carbonate over kaolin. This switch has eroded the share of the market held by kaolin because paper producers partly substitute its use with calcium carbonate, which is less expensive and often brighter. Neutrally sized paper can have higher mineral filler loadings than acid-sized paper, so calcium carbonate slurries are preferred over kaolin slurries because of their higher solids content. Table 5 compares the properties of kaolin and calcium carbonate, both precipitated and ground. Although calcium carbonate is generally brighter than most commercial kaolin, new grades of kaolin for use in paper coating have a brightness of more than 90%.

Ground Calcium Carbonate

Table 6 lists some of the advantages of GCC compared to kaolin usage in alkaline woodfree papermaking. Kaolin was once the most widely used filler in paper manufacture, but the last two decades have seen a steady increase in the use of calcium carbonate. The conversion from acid to alkaline papermaking and the demand for brighter paper have been the main reasons for this change.

Precipitated Calcium Carbonate

World PCC capacity is approximately 6.2 Mtpy, of which almost three-quarters is used in paper. Nearly all of the PCC in paper is used as a filler, and the largest market is the United States. As papermakers transferred to alkaline technology, the number of satellite PCC plants has increased significantly since the first U.S. plant opened in 1986. By 2000, some 80 plants had been installed

Table 5. Comparison among properties of kaolin, PCC, and GCC in papermaking

Property	Kaolin	GCC	PCC
Brightness	80%–85% (some 90%)	>90%–96%	90%–97%
Particle size	Naturally 2 μ m	Requires grinding	Manufactured fine

Source: Harben 1998.

worldwide, with almost 50 in North America alone; the industry is dominated by MTI with 54 plants, followed by Huber Engineered Materials with 12 and Imerys with 6.

PCC manufacturing in Europe is shared between five major producers with an estimated total production capacity of more than 2.0 Mt py in 2003, including products for paper and other applications. The five companies are Huber Engineered Materials with 6 plants, Specialty Minerals Inc. (SMI) with 13 plants, Omya with 4 plants, Solvay with 6 plants, Schaefer Kalk with 3 plants, and Imerys with 1 plant. At the time of this printing, Huber is in the process of selling their 6 PCC plants. The competitiveness of an on-site PCC plant is primarily influenced by the size of the plant (economics of scale) and by the CO₂ content in the gas source from the host paper mill. This means that an on-site satellite PCC plant has to have a certain minimum size and be supplied with a gas of a certain minimum CO₂ content in order to be economically viable. For example, an on-site PCC plant has to process a minimum of 20,000 tpy to be economically justified, corresponding to the demand from paper production of 100,000 tpy of uncoated paper with a 20% filler level.

In Europe, PCC has shown by far the strongest growth rate and since 1995 has continuously taken market share from GCC and other fillers. The growth of PCC is likely to continue with further penetration as filler into the WFU paper segment, although at a slower rate as the market matures.

Some paper mills that had been using GCC derived from chalk in Europe were among the first to capitalize on the added brightness that could be achieved using PCC. Several PCC satellite plants have come onstream in Asia since the mid-1990s, including plants in Thailand, Indonesia, Japan, China, South Korea, and Malaysia. New satellite plants have also been built in South Africa and in South America.

PCC is now making some inroads as filler in groundwood (SC and LWC) papers, and this represents the largest remaining potential market. This market is currently dominated by kaolin and talc, however, especially in European rotogravure paper. MTI has invested much research into developing acid-tolerant PCC, allowing its entry into the groundwood paper sector, for which it now has several satellite plants.

Talc

The choice of filler in paper is driven by cost reduction and quality improvement. For talc, which is more expensive than some other pigments, improving the paper quality and the papermaking process itself is the dominant driving factor. The properties of talc—

Table 6. Advantages of GCC compared to kaolin in alkaline woodfree papermaking

Paper

soft, organophilic, chemically inert, and platy—are reasons why it today is used as filler in many different kinds of paper. The organophilic surface helps reduce dye consumption and two-sidedness in colored paper. *Two-sidedness* in colored paper is the term used to describe the difference in color characteristics between the top side and the bottom side of the sheet. The difference can be either in shade or in strength, or both. Contributing factors are finish, chemical additives, points of addition, order of addition, and colorant characteristics. With careful control of all these factors, however, two-sidedness can be eliminated to result in a uniform sheet.

The relatively coarser particle-size distribution of talc (compared with other pigments) leads to better retention in the sheet and lower effect on the paper's strength properties. Improved dewatering, less wire abrasion, higher retention, a longer life of cutting knives, and fewer core breaks in SCR printing are typical advantages in the process provided by talc. In addition, the pitch and sticky control function reduces tacky deposits and improves paper machine runnability. The paper quality itself is influenced by talc with increased smoothness, better printability, deeper color in colored papers, and a lower impact on strength properties than other fillers.

Other Filler Pigments

Other mineral systems are employed—for example, titanium dioxide. Titanium dioxide is used more as a specialty chemical to impart

specific end-use properties rather than as filler because of its cost. It is used primarily for its opacity properties, particularly in lightweight papers such as paper used for bibles.

A new specialty filler in newsprint is Zeocros PF, produced by Ineos Silicas, a leading global supplier of silica, silicate, and zeolite products. Zeocros PF has a high ISO brightness of 97; small, angular particles with efficient light-scattering surfaces; and a tight particle-size distribution. In newsprint it raises opacity, improves printability, reduces print through/strike through, and enhances brightness. A 1% filler addition will give 0.6 points of opacity increase. Paper with Zeocros also prevents ink penetration into the paper.

Gypsum, or calcium sulfate, is an abundant mineral formed naturally and from industrial by-products (such as flue gas desulfured gypsum and phosphogypsum). It generally has the disadvantage of high solubility, and it also tends to plug machine felts. Calpak C20 is filler derived from gypsum in Spain and is being developed by Kemira. It is a bright filler for a wide range of pH and sizing systems. The production of filler gypsum, however, is limited in the world.

Diatomaceous earth is not filler in the sense of the other pigments but is normally used for pitch control (0.5%–1.5% on pulp), to improve formation, and to increase the rate of drainage, though one serious disadvantage is its abrasiveness.

THE ROLE OF PIGMENTS IN PAPER COATING

Application of Coating Pigments

A coating layer on a paper surface can bring the following improvements to the paper sheet:

- Cover the base paper fibers to give a uniform surface
- Make the paper whiter
- Contribute to the paper's opacity
- Give the desired finish—gloss, silk, or matte
- Give the desired printing properties

A coating mixture, known as a coating color, is normally a mixture of a mineral with a binder to stick the mixture to the paper, a viscosity modifier to assist in the application to the paper surface, and often other chemicals that improve the shade of the coating and its printing properties. An important characteristic for any coating color is good rheological response during metering and application and an ability to retain water during application. An ideal coating mixture needs to be fluid during application, yet immobilize quickly after metering. An ideal coating should cover all the paper fibers. Fiber coverage is often achieved by using high coatweights, coarse particles, platy particles, and coating mixtures that immobilize rapidly.

In paper coating, minerals are used as white pigments to conceal the fiber, thereby improving brightness, whiteness, and opacity, as well as smoothness. If applied by a blade coater, the pigmented layers impart a fairly constant surface layer, but of varying depth as the surface voids and pits of the base sheet are filled in. There is a growing understanding that the filler in the base paper can have a great influence on the behavior of the coating pigment. Application methods such as the air knife and, to a degree, the film press or metering size press provide a coating of more uniform thickness, which follows the larger-scale surface contours of the sheet to give a varying surface level. Such contour coating methods are particularly useful in applying a ground coat to uneven substrates such as folding carton board and corrugating liners.

Coating using the size press is a growing practice, producing paper that bridges the gap between uncoated and full-blown blade-coated products. An extension of this is using high surface area silica or calcium carbonate pigments to provide dye-receptive coatings for inkjet paper (pigment acts as an acceptor of the image

medium). Even in conventional offset lithographic grades, careful development has been undertaken over many years to optimize the ink transfer and drying characteristics of the coatings. In electro-photographic printing grades, controlling surface resistivity and toner adhesion is critical in coatings development. In the Indigo unit with its wet toner system, surface chemistry, specifically acid-base interaction, is critical in image transfer to the paper surface. Matching the pigment formulation to the imaging systems is an increasingly important part of product development, especially in higher value coated paper grades.

The coating formulation must also be optimized for runnability on a high-speed coating line. This requires careful attention to rheology (viscosity at high and low shear). Such parameters are important not only to coating transfer and metering but also to uniformity of the coating in terms of coverage of the fiber in the base sheet. This is vital to print quality. The rheology of the coating is determined by the interactions between the pigment particles themselves and between pigment and binder under the influence of coatings solids content and temperature. Common binders include styrene-butadiene rubber (SBR) latices, starch, acrylics, or vinyl polymers. The rheology can be manipulated by water-phase thickeners such as carboxyl methyl cellulose (CMC) and associative thickeners such as alkali-swellable acrylates or hydrophobically modified urethanes.

In most paper coating, the pigment concentration is higher than the critical pigment binder concentration (CPVC) that is familiar in paint formulations. A blade coating for offset lithographic printing would contain 100 parts pigment to 14 parts binder at 60%–65% solids. A coating for air knife or rod coater application would be about 30%–40% solids. The objective is to create a microporous coating that can facilitate ink transfer. For folding carton board, acrylic and polyvinyl acetate binders are used to increase porosity to permit the use of adhesives on the coated surface. Exceptions to the higher pigment binder ratio are found in barrier coating. Here pigments are used not for their optical properties but to increase the tortuosity of the diffusion path of oils, grease, or water through the barrier. Pigments with high aspect ratios such as platy clay and talc find applications in this area. The addition level is generally about 30–40 parts pigment to 100 parts emulsion polymer, well below the CPVC. A balance has to be struck between adding pigment to boost barrier properties and preserving coating elasticity, so that the paper and board can be folded without cracking the barrier layer.

Table 7 lists pigments used in the coating process and their basic properties. Kaolin and GCC are the major coating pigments, accounting for some 90% of the total. Basically, GCC and kaolin are blended in a wide range of differing coating formulations, depending on the type of paper being manufactured.

Kaolin

Kaolin has a platy morphology that is still required for a large number of paper applications, particularly in lightweight coated papers. The trend in recent years has been to combine different minerals in one coating formulation. Kaolin can be mixed with GCC, with PCC, and more recently, with talc, to obtain improved performance. If a choice is to be made between kaolin and GCC for coating, the papermaker considers the solids percentage (the higher the solids, the less drying of paper necessary), paper brightness, paper opacity, fiber coverage, paper gloss, and print gloss. For high-brightness paper, GCC is used; but for fiber coverage, paper gloss, and print gloss, the platy nature of kaolin is preferable. Kaolin is widely used in paint as an extender, and the calcined grades give higher opacity than a hydrous type. There are regional trends, with the United

Table 7. Properties of pigments used in coating paper

Pigment	Composition	Refractive Index	Specific Gravity	Dry Brightness, %	Average Particle Size D50, μm	Crystal Form

Adapted from Dean 1997.

States still relying dominantly on kaolin for coating, followed by PCC and GCC. In Europe and Asia, the trend has been toward GCC, no doubt because of the proximity of high-quality marble deposits in such places as Carrara in Italy and Ipoh in Malaysia.

The world kaolin market of high-quality beneficiated kaolin was estimated at 25 Mt for 2003 (Wilson 2003, 2004b). The major producing kaolin companies worldwide (Table 8) are led by Imerys with 25% of the market. Leading kaolin-producing countries are the United States, mainly based on the sedimentary deposits in Georgia, with 36%; United Kingdom, 10%; Brazil, 9%; and other countries, 45%. Brazil has shown the most significant growth and is expected to soon overtake the United Kingdom. Large reserves of high-quality coating kaolin discovered in the Amazon Basin have been developed over the past 20 years. These deposits are all sedimentary in origin and are widespread throughout parts of the Amazon Basin. The main operations in the Amazon Basin are CADAM (now owned by Companhia Vale do Rio Doce [CVRD], which is the largest exporter of iron in the world); Para Pigmentos SA (PPSA; now 100% owned by CVRD); and Rio Capim Caulim (RCC; 100% owned by Imerys). In 2005, these three companies had an installed capacity of 2.25 Mtpy, split between CADAM (0.8 Mt), PPSA (0.6 Mt), and RCC (0.8–1.5 Mt). Sales in 2001 brought in revenue of US\$200 million. Proven reserves of kaolin are put at >500 Mt, with CADAM having 270 Mt of ultrafine clay (98 wt % <2 μm); PPSA, 110 Mt of platy clay at 82–85 wt % <2 μm (excluding other reserves that CVRD controls in the same region); and RCC, with 120 Mt of platy-type kaolin at 78–94 wt % <2 μm . Future expansions based on these large high-quality reserves are planned with CADAM aiming to produce 1 Mtpy by 2007; with PPSA, 1 Mtpy; and RCC, 1 Mtpy by mid-2005. CVRD is emerging as the second largest kaolin company in the world, following Imerys.

The world coating clay market is estimated at 8 Mt, of which the major suppliers are the United States, Brazil, and the United Kingdom, with some production from Australia, China, the Czech Republic, Bulgaria, Germany, and France. Coating clays based on sedimentary kaolin sequences in the United States (Georgia), and in the Amazon Basin show a wide range of properties but generally

are clays with a high brightness and good runnability. There are also ranges of platier clays that are either found naturally or can be delaminated from stacky kaolinite found in the deposits.

A range of clays from the United States, Brazil, and Australia is shown in Table 8 and indicates the range of products, whether they have been delaminated or not, and the particle-size distribution.

Imerys, as the largest producer of kaolin with 25% of the world capacity of 25 Mtpy, is the only international kaolin company to produce coating clays from the United States, the United Kingdom, and Brazil; Table 9 shows their range of products.

Table 10 shows a full range of kaolin products covering calcined clays, coating clays, and filler clays for the U.S. producer Thiele Kaolin Company.

New kaolin deposits are being identified in many parts of the world, including Ukraine, Suriname, China, and Australia. Although the coating kaolin market will be dominated by Brazilian and U.S. clays, there is the opportunity for potential new ventures to enter the market. Australia is seen as a likely source of high-quality coating kaolin, with deposits in Western Australia being developed. W.A. Kaolin Holdings Pty (WAK) has acquired the

Figure 3. Scanning electron microscopy (SEM) of the WAK Australian kaolin dynocone underflow showing kaolinite stacks

Figure 4. SEM of WAK-delaminated dynocone overflow platy kaolin

deposits evaluated in great detail by CRA/Rio Tinto in the Wickpin Area, 180 km southeast of Perth. The firm has drilled 621 boreholes in the area, amounting to almost 20,000 m of core. All of this core has been evaluated and models of the deposit prepared. Proved reserves of 100 Mt have been identified with the potential for an additional 300 Mt from 274 km². Full-scale pilot-plant trials were planned for late 2005, leading to a decision on whether a plant will be constructed. The deposit is kaolinized granite with a high kaolin yield of 50% at the <45-µm refining level; by comparison, kaolinized granite from Cornwall shows a 15% yield, reflecting the different levels of felspar in the basement granites-gneisses of Western Australia and the high-level granites of southwest England. Detailed characterization studies have been carried out in U.K., Japanese, and U.S. laboratories, and the potential for high-brightness coating clay has been evaluated in the licoating trials in Finland and elsewhere. This processing has involved cyclone and centrifuge separation with the coarse booklets of kaolinite from the underflows (Figure 3) being subjected to delamination to give a platy product (Figure 4).

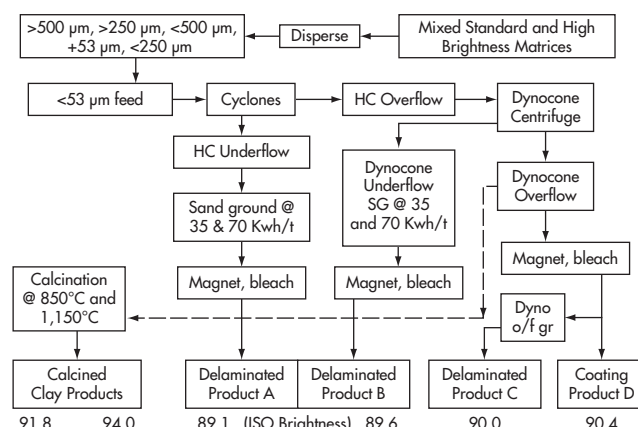

Figure 5. Processing of the WAK kaolin with brightness of various products

For the Chinese market, the high-brightness clays may be blended with GCC in a mix of 70% GCC and 30% kaolin. The Western Australian kaolin can be processed to give a high-brightness delaminated (HBD) coating clay and also as a high-brightness coating clay (Figure 5). Table 11 compares properties of the WAK with Brazilian and U.S. sources, showing the high-brightness values of the WAK clay.

Some Chinese kaolin is suitable for coating clay but, at present, it supplies only the coated board market, not coated paper. A deposit supplying the coated board market is Maoming in Guangdong Province (Zhang et al., 1982; Yuan and Murray 1993; Wilson, Halls, and Spiro 1997; Wilson 2004a).

Kaolin that has been carefully processed to give a controlled particle-size distribution is known as *engineered kaolin*. Ultrafine (less than 0.1 µm) particles are removed to improve light scattering (brightness). These particles are too fine to affect light scatter. Removing such particles does not affect sheet gloss because particles from 1 µm to 0.1 µm have the greatest influence on this property. The disadvantage with engineered kaolin is that the spaces left by the fine particles that have been removed must be filled with water, leading to lower weight-percent solids and less water retention. Because of its higher light scattering, engineered pigments will give improvements in coated sheet brightness and opacity (Table 12).

The shape of the kaolinite particle also influences the coated sheet properties. Pigment shape refers to aspect ratio: the ratio of particle height to width. For a pigment with the same average particle size as measured by a sedigraph, a platy or high-aspect-ratio pigment will impart more fiber coverage when coated. This improved coverage often will result in a smoother coated sheet, which is extremely important for holding dot quality in rotogravure printing. The disadvantage of platy pigments is that the large plate-like particles do not easily flow among one another, giving rise to lower weight-percent solids. The same plate-like characteristics mean, however, that under a coating blade, platy pigments do not lose their water easily.

Ground Calcium Carbonate

Roskill Information Services (2002) estimated that the demand for GCC in papermaking was 15 Mtpy in 2002, with Europe dominating at 67%, followed by Asia and Oceania (22%), North America (8%), and others (3% for Middle East, Africa, and South America).

It can be seen that Europe is a major user of GCC based mainly on marble deposits and also some chalk. Most of the coating market is supplied by products derived from marble deposits, with Omya controlling 75% of the total market and Imerys, Provencale, Reverte, and others accounting for the rest. A major growth market for GCC is now Asia, of which China is at the forefront with many new projects involving satellite GCC plants (for example, APP has a 500,000-tpy GCC plant in Dagang).

Using GCC as a coating pigment gives technical and economic benefits such as high brightness, coating at higher solids, lower binder demand, good runnability, and improved printability. In some applications, the advantage of high-brightness coating pigments leads to lower hiding power and reduced opacity. Therefore, adding opacifying pigments to the coating color to reach the required opacity is common practice. Pigments with high brightness, broad particle-size distribution, and a average particle size of many of the GCCs currently used in coating are not optimal for opacity.

The larger companies such as Omya and Imerys are now producing a range of products for which the GCC is manufactured to optimize the opacity. The new products are produced by a slightly different processing technique: the particle-size distribution and the average particle size are moved according to the theory of light scattering toward that of the ideal opacifying pigment. The processing involves techniques to give steeper curves and in some cases removing finer particles. The percentage of solids at which the processing of the GCC is carried is also important.

Omya has developed a new pigment called Hydrocarb CC. Using the theory of light scattering, Omya designed a pigment with a tailor-made (engineered) mean particle size and particle-size distribution. For high opacity, the target is a narrow particle-size distribution with a mean diameter between 0.6 and 0.8 µm. Using a modified grinding technology, Hydrocarb CC has been manufactured with a narrower particle distribution than Hydrocarb 90. Comparing Hydrocarb 90 and the new pigment shows that the narrow particle size leads to a higher wet void volume and a lower specific surface for Hydrocarb CC. This difference is explained by the reduced amount of fine particles, which results in a more open and porous surface for an increase in ink receptivity. Hydrocarb CC produced from marble shows a higher brightness and opacity on the finished paper compared to Hydrocarb 90 produced from the same source of calcium carbonate.

The choice of mineral pigment used by the papermaker will depend on a number of factors related to the paper grade being produced. These include fiber production costs, mineral pigment price, paper optical properties, and strength. It is significant that the papers considered the best in relative quality terms have the highest mineral content, whether it is by filler content or coating or both. Minerals add value to paper.

Table 13 shows a choice between kaolin and GCC, based on the paper properties. Here GCC is clearly better for color solids and paper brightness but has poorer paper gloss and print gloss than kaolin. The platy nature of the kaolin gives better fiber coverage (especially the coarse platy type for SCA papers), and the fine platy kaolins give good paper gloss and print gloss compared to GCC.

Today the pigments used in paper coating are many and varied in their properties. Blending has become a common feature with precoat often being a coarser GCC (about 60–70 wt % <2 µm) followed by a topcoat with a fine GCC (90–95 wt % <2 µm) blended with either a blocky or platy kaolin dependent on the type of surface required. Very fine clays, such as Amazon Premium, are often blended with 20–50 wt % fine GCC to give a higher brightness surface with enhanced printing properties. Various blends from

pigments such as GCC, PCC, kaolin, and talc are continuously being developed to give the papermaker a wide choice. Table 14 shows some typical blends of kaolin and GCC used for various types of paper.

Unlike the situation in other areas where large players such as Imerys, Engelhard, Huber, Thiele (United States); CADAM and PPSA (Brazil; for kaolin); Omya and Imerys (for GCC); and Specialty Minerals dominate, the Chinese paper pigment market has a larger number of producers for all pigments, with no single company having a sizeable market share. Development of PCC and GCC in China will be dependent on local sources of limestone and marble, respectively, and also the logistics of delivering marble for satellite GCC plants.

The largest paper mill in China is the APP operation at Dagang. Here the pulp is imported from Indonesia and the base paper is manufactured using PCC produced from lime from local limestone in a satellite plant at the paper mill. The precoat is a GCC at approximately 65 wt % <2 μm , followed by a topcoat that is 95 wt % <2 μm GCC, mixed with 30% imported kaolin from the

United States and Brazil. Calcined clay might well be used at the 10% level in the precoat.

Calcined Clay

Soft calcined clays are loosely aggregated as a result of fluxing that occurs on the edges of the particles. This aggregation results in particles of nominally larger sizes but with entrained air voids that give rise to good light-scattering characteristics. These properties are widely used in the paper industry to provide good opacity, ink immobilization, and light-scattering effects. Table 15 shows the main calcined products sold into the paper industry, which is the largest consumer of soft calcined clay products. These are all soft calcined products that are not reactive like metakaolins but have been agglomerated by heating. They have point-contact adhesion, which gives the kaolin platelets a three-dimensional structure; it is this structure that is of benefit to the papermakers: they enhance the optical and printing properties of paper. These products are used in rotogravure applications where low levels of calcined clay improve optics and structure the coating to provide good fiber coverage and

missing dot performance. Calcined clays are also used in newsprint applications to improve the opacity and reduce the consumption of titanium dioxide.

Talc

In Europe, the two main printing processes are rotogravure and offset. The offset process poses problems for the use of talc because the transfer of the image uses a hydrophilic/hydrophobic action, which is largely incompatible with an organophilic mineral like talc. The rotogravure process, however, prints by direct contact between the image cylinder and the paper. Producing printing cylinders is expensive, and, therefore, rotogravure printing is suitable only for large-volume magazines, mail order catalogs, or flyers. Key requirements for rotogravure papers are good spool formation and smoothness. Good spool formation is essential if the printing presses are to run without constant stops. In the early 1970s, papermakers exclusively used platy English and German clays, and then added U.S. delaminated clays. In the late 1970s, the research department at Finminerals (now Mondo Minerals) began working with large Finnish customers to develop talc grades suitable for coating; in 1981 they launched their product. This was followed by Luzenac introducing a rotogravure-coating talc. The talc works in two ways to improve rotogravure paper. First, its low coefficient of friction allows the large spools to be produced with a constant tension, which reduces paper breaks; and second, because talc is very platy, it helps improve the smoothness and therefore gives better printability. Talc has successfully established itself as a major coating mineral for rotogravure paper (Whiteley 2002).

Precipitated Calcium Carbonate

PCC is well accepted as a filler pigment and is now beginning to be used as a coating pigment. Currently, PCC accounts for less than 5% of coating pigments used but the market is developing, led by SMI, Imerys, and Omya. SMI, part of Minerals Technologies, pioneered the concept of the satellite plant for PCC and now has more than 50 plants in operation around the world. PCC is valued for its high brightness and light-scattering characteristic in paper filling and coating applications. PCC is produced through a reaction process that uses very pure calcium carbonate crystals and water. The crystals can be produced in a variety of different shapes and sizes, depending on the specific reaction process that is used. The two main raw materials required are quicklime and carbon dioxide. Because quicklime is readily available in many areas of the world, it can be delivered to the satellite plant at a reasonable cost. In most paper mills, carbon dioxide is available to be used from a mill flue gas. This makes PCC economically attractive for the paper mill.

For paper coating, SMI developed several PCC product lines—ALBAGLOS, OPACARB, and JETCOAT. ALBAGLOS has a precisely controlled particle-size distribution, good high-shear rheology, and good ink hold-out, and it can be used at high levels to improve paper brightness and opacity while maintaining sheet gloss. OPACARB has an acicular shape that provides good smoothness, gloss, brightness, and opacity owing to a narrow particle-size distribution and a mean particle size of 0.40 μm . JETCOAT is the latest PCC coating pigment and is designed specifically for coating inkjet and other nonimpact papers. SMI has developed six different commercial crystal shapes of PCC that give a wide variety of crystal structures that offer different performance characteristics (brightness, opacity, and bulk) to a sheet of paper. These shapes are scalenohedral calcite, spherical calcite, prismatic calcite, clustered acicular aragonite, rhombohedral calcite, and discrete acicular ara-

gonite. Using crystal-engineered PCC can also improve paper machine productivity.

Imerys produces a broad range of PCC products for filling, precoating, and top/single coating, applicable in all paper and board-manufacturing processes. Imerys's PCC coating products include Opti-Cal Print (rhombohedral), with a mean particle size (mps) of 0.5–0.7 μm and a brightness of 95–98 GE. Opti-Cal Matte is rhombohedral with an mps of 2.0–2.2 μm and Opti-Cal Gloss is aragonite with an mps of 0.3–0.5 μm and a brightness of 95–98 GE. Imerys was chosen by M-real, one of Europe's foremost producers of P&W papers (ranked first in WFC paper, and second in WFU paper), as the supplier of calcium carbonates for its paper mill in Husum, Sweden, which has a capacity of 620 ktpy. Under a long-term contract, Imerys completed construction in 2005 of a satellite PCC plant at M-real's Husum facility.

Blanc Fixe

Blanc fixe (meaning *stable white*) is a synthetic barium sulfate that is precipitated with a defined particle size from highly purified solutions of barium salts and sodium sulfate. Because of its chemical production process, blanc fixe is free of impurities such as quartz. The feed material for the process is chemical-grade barite (BaSO_4), which is generally low in silica. Much of the chemical-grade barites used in Europe for blanc fixe production come from China. With its hardness of 3 on the Mohs scale, blanc fixe has low abrasion and exhibits an extremely high light reflectance in broad ranges of the spectrum, not only in the visible but also well into the ultraviolet and infrared ranges. Blanc fixe is generally 99% BaSO_4 with an average particle size of 3 μm , a lightness/color of 98.5 (on the International Commission on Illumination [CIE] $L^*a^*b^*$ color system), and a pH of 9. It is used both in pulp and as a pigment in coating because of its color and low binder requirements. It is used in small amounts in coated art papers and in photographic papers, where it was applied to the base to improve the surface before the light-sensitive photographic emulsion is applied. The development of extrusion coating involving special plastics that do not absorb the processing chemicals, however, has generally replaced this precoat, especially for color printing paper.

Satin White

Satin white, a calcium sulfo-aluminate, is one of the oldest known pigments for paper. Manufacture involves reacting alum with slaked lime at a controlled temperature. Satin white forms acicular crystals that are often 1–2 μm long and 0.1–0.2 μm in cross section. This shape imparts an open, bulky structure to the coating that has a major influence on its optical properties; in particular, it is responsible for high-gloss development during calendering as well as giving a high print gloss, high ink receptivity, high bulk, and good covering power. A 4-g/m² coating of satin white would have a similar covering power to a 10-g/m² clay coating. Satin white, however, has a very high dispersant demand because of calcium ions in solution. It also leads to high adhesive demand if the satin white level exceeds 10%. The main applications for satin white are in high-quality art paper and high-quality lightweight offset grades.

Titanium Dioxide

TiO₂ offers the highest opacity and hiding power of all coating pigments, giving good optical density, excellent brightness, and very low grit levels (0.0010–0.0050 wt % of <325 mesh). High brightness, combined with superior light scattering, provides excellent brightness and whiteness to paper and paperboard products. TiO₂ provides the best opacifying performance available to the paper industry because of highly efficient light scattering. The higher the TiO₂ g/m²

Adapted from Haarla 2002.

Figure 6. Western European newsprint and writing paper consumption, Mtpy

light scattering, the less TiO_2 needed to achieve the opacity target. The high refractive index of the rutile TiO_2 crystal proves an inherent light scattering advantage over anatase TiO_2 . The median particle size of TiO_2 coating pigments is very fine at just 0.30–0.60 μm .

THE FUTURE

Pigments for paper will continue to be a growth industry over the next decade, particularly in China, where production is expected to grow from 33 Mtpy to 80 Mtpy by 2015 (M. Sang, personal communication). In Western Europe, paper consumption increased significantly from 1950 to 2000, despite innovations such as television, computers, and the Internet that were expected to lead to a paperless society (Figure 6). Unless there is a dramatic shortage of fiber in the world for some unknown reason, papermaking, particularly the uncoated woodfree papers, is expected to grow.

Kaolin competes with GCC, PCC, and talc in the paper industry. In 1980, kaolin accounted for 87% of the pigment used in paper (10.2 Mt), whereas in 2000 this had fallen to 40% when the total pigment used in paper was 29.9 Mt. During the same period, GCC's market share grew from 9% to 33% and PCC use grew from virtually zero to a 14% market share (Haarla 2002). This trend toward calcium carbonate has mainly been a result of an alkaline papermaking system replacing an acid system, and also because of the requirements of higher brightness pigments for woodfree pulp.

These changes have been in a market that has grown significantly, however, so the tonnages that the kaolin companies supply have remained much the same over the last decade. The supply of kaolin has switched from the United States and the United Kingdom to Brazil with the discovery and development of world-class facilities based on the sedimentary kaolin deposits in the Amazon Basin.

There will be no shortage of pigments in the world for the next 100 years at least. New kaolin deposits in the Amazon Basin, Western Australia, and elsewhere are being discovered, and potential resources are very large. The Cornish kaolin deposits mined for more than 250 years have just another 40–50 years of reserves left. There is sufficient suitable limestone available to manufacture lime for PCC production, and the use of GCC, which relies mainly on good sources of marble, is expected to grow. Although there might well be some shortages of high-quality marble in some parts of the world, increased processing such as flotation to remove silicates, graphite, and iron pyrites will allow the use of lower quality marble

deposits. New deposits of anatase and rutile are being discovered and developed, which means no shortage of titanium dioxide.

The real value of minerals used in papermaking lies in their capability to further improve printing results and enable the paper or board substrate to be a good printing surface. Developing higher brightness, whiteness, and opacity remains a challenge, especially as papers and boards trend to lower basis weights and sheet thickness. The digital revolution has enabled almost everyone to access text and pictures that can then be used to produce an infinite variety of printed media. This capability has created new requirements for paper and board surface properties than can be satisfied not only by surface-applied pigments but also by the use of fillers to improve base sheet uniformity. Developing filled barrier coatings is also an emerging opportunity.

Paint and Coatings

Peter A. Ciullo

At the dawn of the industrial revolution, artisans used paints and varnishes for both decorative and protective purposes. By the late nineteenth century, mechanization and the widespread use of iron and steel helped transform the production of coatings from an art to an industry. Ferrous fabrications required anticorrosive and protective coatings and the need for architectural coatings grew with the size of cities, so paint factories were established in industrial and population centers. Initially, very few scientifically trained personnel worked in the industry, but between the world wars of the twentieth century, the accelerating pace of technological development—particularly the manufacture of titanium dioxide (TiO_2), developments in alkyd chemistry, and the mass production of automobiles—catalyzed research into coatings of all types. The post-World War II era can be characterized as the gradual and ongoing conversion to solventless coatings technology. Although the first latex paint was introduced in the late 1940s to only moderate success, water-based systems have since undergone continuous improvement and are now as durable for many uses as their solvent-based counterparts. Today, industrial finishes that are free of both solvent and water are common.

The annual production of paints and coatings in the United States is approximately 1.3 billion gallons (Anon. 2002), and Table 1 compares the production volume of the major categories of coatings by type and form. Multinational corporations dominate the worldwide paint and coatings industry. More of the world's leading producers are headquartered in the United States than in any other country, but the size of the North America market for architectural and industrial coatings, particularly those for the automotive industry, has resulted in considerable participation by foreign companies, including their establishment of manufacturing facilities in North America (Anon. 2003). Of the approximately \$16 billion in annual U.S. shipments of paint, varnish, and lacquer, only 2.5% is imported and nearly 7% is exported (Anon. 2002).

RAW MATERIALS

The coatings formulator chooses raw materials from the following basic categories:

- **Extender pigments:** These are the minerals used to optimize the pigmentation efficiency of TiO_2 , improve film properties, and reduce cost.
- **Pigments:** Inorganic and organic pigments are added principally to impart a particular color.

- **Binders:** The binder forms the continuous coating film. It literally binds the pigment and extender particles within the film.
- **Solvents:** Solvents are needed in liquid coatings to solubilize or disperse the binder. The solvent is lost to evaporation during film formation.
- **Additives:** Additives is a broad category encompassing many chemicals and several minerals used to optimize coatings properties before, during, and after cure.

EXTENDER PIGMENTS

Traditionally, fine-ground minerals have been used in paints as inexpensive fillers—they extend the film formed by the generally more expensive binder. Most minerals are now more appropriately used as functional fillers. They are chosen to benefit coating stability, rheology, and application properties, and to enhance dry film properties. Very fine particle-size minerals are used as pigment extenders in a more literal sense, extending the optical value of TiO_2 , the predominant white opacifying pigment in coatings. These extenders effectively separate the individual TiO_2 particles and provide the optimum pigment spacing for maximum opacifying effect. Pigment extenders are used in this way to reduce the amount of relatively expensive TiO_2 required for a given level of opacification and whiteness. The major extender minerals are calcium carbonate, talc, kaolin, silica, barite, wollastonite, nepheline syenite, and mica. Lesser use is made of diatomite, feldspar, perlite, and pyrophyllite.

Important Properties

The performance properties of an extender pigment are influenced by its volume fraction in the coating matrix (pigment volume concentration [PVC]), its particle shape and particle size, and its adhesion to the binder.

Volume Fraction

The volume fraction of the extender pigment, or its PVC, is the volume it occupies divided by the volume of the dry coating film. These minerals usually exert their strongest overall influence on coating properties when there is just enough binder to coat all particles and fill interparticle voids. In coatings, this occurs at the critical pigment volume concentration (CPVC). Film properties change rapidly near the CPVC, where film density, tensile strength, and adhesion tend to reach a maximum. At PVCs above the CPVC,

Table 1. Annual coatings production, selected categories

Category	Gallons (x1,000)
Architectural Coatings	
Exterior, solvent-thinned	70,967
Exterior, water-thinned	182,423
Interior, solvent-thinned	48,947
Interior, water thinned	407,104

Architectural	10,310
Lawn and garden	12,170
General metal finishing	111,015
Other industrial finishes	192,425

there is not enough binder to completely fill the voids between the pigment particles. The film becomes more permeable, with consequent reduction in scrub resistance, stain resistance, rust inhibition, enamel holdout, and blistering. As the CPVC is approached and exceeded, the pigment particles progressively disrupt the smoothness of the film surface, causing light to be scattered and gloss to be reduced. CPVC usually occurs between 40% and 55% PVC.

Particle Size and Shape

Extender pigment particles can be described by three basic shapes: (1) blocky, as with calcium carbonate, silica, and nepheline syenite; (2) platy, as with talc, mica, and kaolin; and (3) acicular, as with wollastonite. Platy and acicular particles are further characterized by aspect ratio. For platy particles, the aspect ratio is the ratio of the mean diameter of a circle of the same area as the face of the plate to the mean thickness of the plate. For acicular particles, it is the ratio of mean length to mean diameter.

For a mineral to contribute to the mechanical properties of a coating film, stress, as from stretching or bending, must be transferred from the polymeric film to the strong and stiff mineral. The stress transfer is more efficient if the mineral particles are smaller, because for a given concentration, greater mineral surface is exposed to intercept the stress. Effective stress transfer also requires intimate mineral-binder contact and a certain minimum aspect

ratio. Once this ratio is exceeded, the efficiency of stress transfer increases with increasing aspect ratio.

Although small particle size and large surface area improve the durability of a coating film, they also promote high vehicle demand, which lowers CPVC and limits loading levels. The balance of film reinforcement and vehicle demand can be controlled by the choice of mineral, by the particle-size distribution of the mineral, and by the use of combinations of minerals. High aspect ratio particles tend to pack in such a way as to create larger interstices, which fill with binder, as opposed to low aspect ratio or blocky particles. Platy and acicular extenders, therefore, are generally produced with a broad distribution of particle sizes. The finer particles fill within the interstices of the larger ones, displacing binder and increasing CPVC, without compromising the mechanical properties of the coating film. With extenders of narrow size distribution and high aspect ratio (HAR), this purpose can be served by the primary pigments and by the inclusion of low-cost, fine-ground blocky fillers such as calcium carbonate and silica.

Binder-to-Mineral Adhesion

Intimate mineral-binder contact is important in optimizing extender pigment performance. The pigments may be well dispersed throughout a coatings film, but any gaps at the mineral-binder interface represent areas of zero strength and locations for the transmission or collection of moisture and other liquids. This is analogous to the effects on permeability and film strength of exceeding the CPVC.

Solvent- and waterborne coatings present significantly different considerations regarding the intimacy of binder-to-filler contact and adhesion. In the former, the mineral is already wetted by and dispersed throughout an organic medium. As volatiles are lost and the film contracts, the mineral particles become more closely packed and are ultimately encapsulated in the final binder film. In an emulsion coating such as a latex paint, the mineral particles are wetted by water that contains surfactants and dispersing agents designed to make the particles hydrophilic and resistant to agglomeration. The dispersed mineral particles share the aqueous medium with dispersed binder micelles. As volatiles are lost, the binder micelles coalesce into a continuous polymeric film. In so doing, they must deform around, displace water from, and coat the mineral surfaces. This process is consequently less conducive to intimate binder-mineral contact than that of solvent paints.

Surface treatments and modifications are used as necessary to optimize a mineral's compatibility with and adhesion to the binder matrix. Although a mineral to which any type of organic chemical has been added is commonly called "surface treated," a surface treatment can be differentiated from a surface modification on the basis of functionality. A surface-treated filler is coated with a processing aid. A processing aid may not bond to the filler and does not bond to the matrix. It acts as a wetting agent to make the filler surface hydrophobic and more intimately coated by the organic medium. Surface treatments improve deagglomeration and dispersion in organic media, promote better coating of mineral by binder, and allow higher filler loadings. Stearic acid is a common treatment on calcium carbonate. Organosilanes with nonreactive organic groups are sometimes used as treatments on silica and silicate extenders.

A surface-modified filler has a coupling agent covalently bonded to its surface. The coupling agent is in turn bound to the matrix through chemical reaction or chain entanglement. The coupling agents used as surface modifiers perform the same functions as surface treatments and, in addition, improve binder adhesion, film integrity, weathering, and service life. The most commonly used modifiers are the organosilanes with amino, epoxy, methacrylate, or

vinyl functionality. Silane treatment levels are typically 0.5% to 1.0% of mineral weight.

Oil Absorption

The oil absorption of an extender pigment is measured to reflect the composite effect of particle shape, particle-size distribution, surface area, the effect of mineral PVC on CPVC, and mineral-binder interaction. The coatings formulator often uses oil absorption values as a guide to selecting the optimum combination of pigments and extender pigments.

The spatula rub-out oil absorption test (ASTM D281) is used to indicate binder demand by determining the amount of linseed oil that is just sufficient to coat the mineral particles and fill the interparticle interstices. The first component of the test is the amount of oil required to wet and coat the mineral particles. This depends on surface area, which is affected by particle-size distribution; hydrophilicity, which can be adjusted by surface treatment or surface modification; and porosity, which is a result of mineral lattice structure. Surface treatment or modification, for example, can reduce oil absorption and raise the CPVC of a mineral that is otherwise an appropriate shape and size distribution. After the particles are coated with linseed oil, the second component of oil absorption is the additional oil that fills the interstices. In effect, this test measures the CPVC of the mineral-linseed oil composite and has some value in indicating the mineral's CPVC in a coating.

The following equation is often cited to relate oil absorption to CPVC:

$$\text{CPVC} = 1 \div [1 + (OA \times p)/93.5]$$

where *OA* is the oil absorption and *p* is the specific gravity of the mineral (Hare 1994). This is generally considered to be a good predictor of CPVC in solvent paints. This formula overstates somewhat the CPVC expected in latex films because of the different mechanism of filler integration, as previously described. From this equation, nevertheless, comes an appreciation of the effect of a filler's specific gravity, or weight per gallon, on CPVC: for a given oil absorption, a higher specific gravity results in a lower CPVC. This relationship is easily overlooked because the high specific gravity pigments and extenders, such as TiO₂ and barite, are often lower in oil absorption than low specific gravity alternatives. Because paints are sold by volume rather than by weight, specific gravity is taken into account along with cost per pound when the overall economics of the coating formulation are considered.

The oil absorption values of individual pigments and extenders can indicate the relative effects of these components on CPVC. When formulating for PVC versus CPVC with a particular combination of pigments and extenders, however, aggregate surface areas, specific gravities, and packing geometries must be considered. Oil absorption of the blend must therefore be measured because the contribution of the individual components is not additive.

Mineral Extenders

Table 2 compares the extender mineral basic properties of interest to the coatings formulator, and Table 3 compares their relative advantages in contributing to film mechanical and optical properties.

Calcium Carbonate

Calcium carbonates are more widely used in paint and coatings systems on a weight basis than any other mineral extender. The ground natural products have a long history of use because they are relatively inexpensive, are white, and have low vehicle demand. These attributes make high loadings both possible and attractive. These materials are used to reduce the cost of many formulations

Table 2. Extender pigment basic properties

Extender Pigment	Specific Gravity	Refractive Index	Mohs Hardness	pH
Calcium carbonate	2.7	1.66	3	8.5
Talc, platy	2.8	1.59	1	9.5
Talc, tremolitic	2.6–3.1	1.57–1.62	3.5	9.5
Kaolin, hydrous	2.6	1.56	2	4–8
Kaolin, calcined	2.5–2.6	1.62	3–4	5–6
Silica	2.6	1.54	7	7
Barite	4.5	1.64	3–3.5	7
Wollastonite	2.9	1.63	5–5.5	10
Nepheline syenite	2.6	1.53	5.5–6	10
Feldspar	2.6	1.53	6–6.5	8–9
Mica	2.8	1.6	2–2.5	7–9
Diatomite	2.2	1.45	5.5–6	7
Pyrophyllite	2.6–2.9	1.54–1.6	5	7
Perlite	2.6	1.49	5.5–7	7

while improving both the rheological and mechanical properties of the coating.

Ground natural products are used extensively in solvent-borne exterior house paints and interior flats and semigloss enamels. The higher vehicle demand of the precipitated calcium carbonates (PCCs) limits the use of these materials in nonaqueous systems, although small amounts are used as flow-control agents. In water-bornes, the hydrophilic nature and low water demand enable the easy incorporation of high levels of calcium carbonate with only minor increases in viscosity. High brightness ultrafine-ground PCCs are used as TiO₂ extenders and opacifiers in waterborne coatings. They have a higher binder demand than coarser grades but better dry hide and gloss retention. The alkalinity of calcium carbonate is an advantage for in-can buffering and in corrosion control coatings. It can be a disadvantage in protective coatings, however, because of its reactivity with acids and its consequent sensitivity to acid rain.

Talc

Talc products are perhaps the most broadly functional of the extender pigments. Although exterior house paint is the major coatings application for talc, talc is probably used in a wider variety of coatings than any other mineral. Talc products serve as extender pigments in solvent-borne and waterborne architectural and industrial primers and topcoats, and in powder coatings.

The products used in coatings are platy talc, containing predominantly (>90%) the mineral talc, and tremolitic talc, most often a natural blend of platy talc and serpentine, plus acicular/blocky tremolite and anthophyllite. Platy talcs can be further classified as microcrystalline or macrocrystalline. Microcrystalline varieties are naturally small in plate size and are the product of compact, dense ores. Macrocrystalline varieties contain relatively large, higher aspect ratio plates. Because talc is a very soft, platy mineral, the residual minerals in platy talc products can have a subtle effect on properties. Carbonates, for example, being nodular and relatively hard, might require more grinding than a softer, platy chlorite in order for a talc product to attain a particular Hegman fineness. Tremolitic talcs, however, exploit the properties contributed by the significant amount of accessory minerals that occur together with the talc.

The value of platy talc in coatings accrues primarily from its particle shape and surface properties. Talc is hydrophobic, but it

* gr = natural, ground; pt = precipitated; dl = delaminated; cc = calcined; tr = tremolitic; pl = platy.

disperses easily in aqueous as well as solvent-borne coatings. With its platy shape, talc has a beneficial effect on paint rheology. It generally contributes to improved brushability, leveling, and sag resistance. It is normally self-suspending in paint vehicles and assists in keeping other pigments suspended. When settling does occur, it is generally soft and readily redispersed.

Platy talcs improve the toughness and general durability of paint films. The talc plates tend to align with the coating's flow so that they are parallel to the substrate in the dry film. This creates a physical barrier to the transmission of moisture, improving water and humidity resistance. The relative impermeability, however, can increase the formation of blisters as any moisture or gases leave the substrate. Platy talc reinforces the dry coating film because of its alignment therein and its naturally high aspect ratio. Reinforcement makes the film more resistant to cracking or rupture in response to stretching and flexing, thus better insulating the substrate from the environment. The combination of barrier properties, alkaline pH, and reinforcement accounts for talc's contribution to corrosion inhibition. Its barrier properties also make platy talc well-suited for primers and sanding sealers used on porous substrates to control penetration. In exterior paints, platy talcs tend to chalk more readily than most extender pigments, although less than calcium carbonate.

In liquid coatings, 325-mesh or 4-Hegman talcs are most commonly used. The micronized talcs, 6 Hegman or finer, are used for TiO₂ extension, good low angle sheen, and good burnishing resistance. Macrocrystalline varieties are preferred for the ir excellent flatting.

Tremolitic talc is used as an alternative to platy talc in many coatings applications, with the heterogeneous mineral blend accounting for its functional differences. The combination of acicular, blocky, and platy particles, ranging in size down to the clay-like serpentines, allows for softer settling, easier redispersion, and

higher loading levels. These factors also allow for better light scattering and thus better color in oil and better dry hide. Flatting efficiency is generally inferior to that of platy talcs. The hardness of the nontalc constituents provides greater scrub resistance and durability (Ciullo and Anderson 2002). In primers, the variety of particle shapes provides more microroughness than do flat plates and thus better intercoat adhesion.

Tremolitic talc often provides better film reinforcement but somewhat greater permeability than platy talc. Barrier properties are generally not as good, but this reduces the tendency to blister. For corrosion control, greater permeability is compensated for by greater alkalinity in addition to film durability. Tremolitic talcs with 4 Hegman fineness are the most widely used grades in architectural, industrial, and marine coatings.

Kaolin

Kaolin has a platy structure, but unlike talc, its use in coatings derives more from its contribution to optical properties than to physical properties. Because of the importance of kaolin's effect on the optical properties of coatings, these clays are offered in more varieties than are other extender pigments to provide a range of particle sizes and shapes, controlled particle-size fractions, brightness, and opacification. For example, the thin, wide individual plates of delaminated clay, from a coarse water-washed clay fraction, provide improved brightness, opacity, and barrier properties. Low-temperature calcination of water-washed clay increases hardness, porosity, brightness, opacity, and oil absorption. High-temperature calcination maximizes brightness and opacity. The balance of opacity and sheen derived from calcined clays is further manipulated by the temperature, rate of heating, and fluxes used in the calcination process.

These clays are made even more versatile through chemical modification. Grades are available with dispersant coatings for easy

dispersion in water, as well as stearate or silane surface treatment or modification for improved compatibility with organic matrices. "Structured" clay products, in some cases also called SAMS (synthetic alkali metal aluminosilicates), are made by reacting kaolin with alkalies, such as alkaline silicates, under elevated temperatures and pressures. The resulting alkaline products are essentially kaolin plates with a rim of amorphous reaction product. The reaction and subsequent agglomeration can be conducted to provide products with increased but controlled levels of porosity, oil absorption, brightness, opacification, tinting strength, and flattening (Broom 1997). A different approach to structured pigments for better optical properties is to electrostatically bind oxide particles such as silica or titania to clay faces.

The primary use of kaolin in coatings is as a TiO_2 extender in water-based architectural paints. Calcined clays generally provide the best brightness, TiO_2 extension, and dry hide. Water-washed and delaminated grades also contribute to extension and dry hide, as well as covering power and gloss control.

Despite the fact that the coatings industry focuses primarily on the optical properties of kaolin clays, this mineral also serves as a functional filler (Stoneback 1996). Water-washed clays are used for their contribution to suspension stability, flow properties, leveling, film smoothness, film strength, and weather ability. Delaminated clays are preferred for improved barrier properties and for more controlled chalking and overall durability in exterior coatings. Because of their greater hardness, calcined clays provide better scrub resistance, which is otherwise not improved with kaolins.

Silica

Ground quartz is used in a wide variety of trade sales paints and liquid and powder industrial coatings as a relatively low-cost, high-brightness extender. It is produced in controlled particle-size distributions for low binder demand. It is chemically inert for good acid, chemical, and heat resistance, and its hardness improves abrasion resistance. Ground quartz is especially suited for primers where surface hardness and roughness are desirable. Its presence in exterior solvent-borne paints improves weatherability in a wide range of environments. It also improves the wear resistance of deck enamels and traffic paints. The particle shape of novaculite, a platy natural silica, imparts additional mar, wear, and weather resistance. Using micronized silica in interior and exterior latex coatings increases surface uniformity and provides efficient flattening. Precipitated silicas are used in coatings to provide flattening, mar resistance, and abrasion resistance. Synthetic silicas are also used as flattening agents in clear coatings because their low refractive index makes them transparent in the film.

Barite

Barium sulfate is used in coatings as barite (known as barites in the United Kingdom), in its natural mineral form, and as *blanc fixe*. *Blanc fixe* is made by reducing barite with coal to barium sulfide, which is then dissolved and reacted with sodium sulfate to precipitate barium sulfate. Barite is used for its low oil absorption; high density; low abrasiveness; chemical inertness; heat resistance; high brightness; lightfastness; low solubility in water, acids, and alkalis; and for its low absorbance over a broad spectral band from near infrared to near ultraviolet. *Blanc fixe* is the preferred form when higher brightness and purity and finer particle size are required.

Blanc fixe and finely ground barite are widely used in industrial coatings, particularly in automotive, marine, and aerospace primers and topcoats. Low oil absorption allows high loadings with a minimal effect on rheology. The high filling level results in a smooth nonporous primer surface with good sanding properties and

excellent gloss retention for subsequent topcoats. In topcoats, these extenders improve flow properties, surface hardness, and color stability. *Blanc fixe* is preferred for glossy topcoats and generally for TiO_2 extension. Barite is widely used for high wear resistance in powder coatings.

Blanc fixe and finely ground barite are also used as extenders for waterborne paints, particularly those requiring a high level of gloss and minimum color distortion. The high refractive index of these materials allows them to function as a translucent white pigment in latex paints, providing a moderate degree of hiding power while having a minimal effect on the color of the primary pigment. The chemical resistance of barium sulfate imparts good weathering characteristics to both solvent-borne and waterborne exterior paints. High specific gravity makes the barium sulfate extenders somewhat more difficult to maintain in suspension compared to other minerals.

Wollastonite

Wollastonite is unique among extender pigments, combining naturally high brightness for cleaner tints; needle-like particles for low sheen and film reinforcement; moderate hardness for wear resistance; moderate oil absorption for higher PVC contribution; and alkaline pH for in-can buffering and flash rust, corrosion, and mildew resistance. The most common use of wollastonite is in corrosion-resistant coatings, particularly waterborne epoxies, where it acts as a synergist with primary inhibitive pigments (Jackson 1990; Hare 1997). Silane-treated fine ground and micronized grades are preferred. In barrier-type formulations where corrosion resistance is achieved through means other than inhibitive pigments, wollastonite is effective on its own. In addition to providing alkalinity, surface-modified grades, typically with aminosilane or epoxysilane, control ionic permeability of the coating film by ensuring against voids at the binder-mineral interface, and by reinforcing the film, reducing film failure caused by mechanical stress, impact, and abrasion.

In addition to corrosion control applications, powder and HAR acicular grades of wollastonite are used in architectural, industrial, and marine coatings to ensure film integrity when exposed to physical and environmental assault. The hardness and acicular shape of wollastonite particles, even at low aspect ratios, reinforce coating films, providing durability and flexibility as well as good mar, scrub, and abrasion resistance. HAR wollastonite grades are used in thick build systems—asphalt coatings, coal tar coatings, texture coatings, and block fillers—for mechanical strength, mud-crack resistance, and durability. Wollastonite is also used in epoxy powder coatings because its low binder demand promotes smooth flow, water resistance, improved adhesion, and good chip resistance. Coarser, more acicular grades are used in primers because they provide a microtextured surface with good tooth for finish coats. In decorative powder coatings, fine-ground and micronized wollastonites are used to provide a smooth satin finish.

Nepheline Syenite and Feldspar

Nepheline syenite and feldspar are unique among low aspect ratio extender pigments for the combination of physical and optical properties that they provide. Milled nepheline syenite and feldspars are composed of angular blocky particles. This shape, with its attendant low surface area, accounts for easy dispersibility, low vehicle demand, and the ability to achieve high loadings. The shape and size distribution of these particles can significantly improve the integrity of dried film through their ability to interlock and pack more tightly and rigidly than smooth surfaced spherical or nodular fillers. The likewise promote flattening and uniform low-angle

sheen. Dry film durability confers crack resistance, and, in combination with relatively high mineral hardness, provides high abrasion, scrub, and burnish resistance. Coatings grades of nepheline syenite and feldspar products are differentiated primarily by particle-size distribution, which in turn determines surface area, oil absorption, and Hegman fineness.

Feldspar and nepheline syenite have very low tint strength, contributing minimal color at high loadings, thus allowing the maximum development of deep tone and pastel colors with minimal colorant. Film reinforcement, chemical stability, and resistance to chalking promote retention of tint and gloss on prolonged exterior exposure. A 4-Hegman grind of nepheline syenite is typically used to achieve the optimal balance of properties. The low refractive index of nepheline syenite and feldspar allows for higher loadings in clear and semitransparent coatings and stains.

Nepheline syenite is often favored over feldspar in coatings because it is silica-free and an effective alkaline in-can buffer. If an exterior latex coating is sufficiently permeable, however, the nepheline component is subject to attack by acid rain and acidic atmospheric moisture. This can eventually result in the frosting of deep tones. Feldspar is preferred in this case. An application of emerging interest for nepheline syenite is powder coatings, where hardness and low resin demand allow for high loadings, low-melt viscosity, and improved abrasion resistance (Keegan 1999).

Mica

The primary coatings use of mica is as nacreous pigment in automotive paint. The grades used as a platy extender pigment are generally higher in aspect ratio, more flexible, more hydrophilic, higher in binder demand, and inferior in color compared to platy talc. Because mica plates are generally stronger and less brittle than the particles of talc and clays, they are more resistant to breakage and reduction in aspect ratio under high-intensity mixing or milling. Mica does not delaminate quite as readily as talc, so it is somewhat harder, although still softer and less abrasive than most other extender minerals, minimizing its contribution to scrub and abrasion resistance. Its high aspect ratio and platy shape provide excellent film reinforcement.

Fine-ground and micronized mica is used as a functional extender in a variety of paint and coating formulations. As a platy mineral, it has beneficial rheological properties in liquid coatings, and also helps reduce sagging once the coating is applied. Mica reinforces the paint film during drying and curing, and as the film ages, it reduces the internal stresses from oxidation, and thermal expansion contraction. Mica increases the film's flexibility and reduces cracking and checking, resulting in improved adhesion and better weathering. Film reinforcement therefore accounts for mica's utility in a broad spectrum of coatings, from texture paints to exterior coatings.

Because its flakes align parallel to the substrate, mica is used in roof coatings, exterior wood stains, and exterior paints to control moisture and gas permeability and to reduce light penetration in the coating film. This makes the film more resistant to fading, weathering, and ultraviolet (UV) degradation. Mica's barrier properties are also exploited in primers, anticorrosion paints, and marine coatings. The ability of mica plates to overlap and bridge openings is used for penetration control in sealers for porous surfaces. Other typical filler uses are in floor and porch paints, heat-resistant paints, and traffic paints. Mica's relatively low brightness and high binder demand necessitate low loading levels in most decorative coatings.

Diatomite

White, flux-calcined diatomite is used as a functional extender and flattening agent. The varied size, shape, and high surface area of the

individual particles result in irregular texturing of the coating surface. This reduces surface gloss and improves adhesion of subsequent coats. Diatomite is used in coatings for uniform control of gloss on irregular surfaces, improved sanding properties, and increased film vapor permeability. The last promotes more rapid drying and reduced blistering and peeling. Diatomite's inherent absorbency reduces resistance to staining and soiling.

Pyrophyllite

Typical of commercial pyrophyllite, this mineral is not necessarily the major component of products sold under its name. Relatively coarse-ground grades are used to impart mud-crack resistance to high-build coatings such as textured paints and block fillers, and checking, cracking, and frosting resistance to exterior latex paints. The platy nature of the pyrophyllite, mica, and kaolin components promotes good dispersion by inhibiting the settling of pigments, helps film dry, and increases resistance to film cracking. The considerable quartz content of these products contributes hardness and wear resistance. Fine-ground grades have also been considered for use in powder coatings and traffic paints. The combination of soft platy and hard blocky particles in pyrophyllite products provides unique performance possibilities in coatings, but their generally off-white color and the safety concern relating to their high quartz content (up to 60%) inhibit widespread use.

Perlite

Perlite is a chemically inert flattening filler with high oil absorption and good dry hide. Expanded perlite is used in lightweight fire-resistant coatings for structural steel and concrete, as a filler in textured paints, and in auto underbody plastisol coatings to reduce weight and improve sound insulation. Expanded perlite is milled and sized to fine particles with jagged interlocking shapes that promote good film integrity and substrate adhesion.

PIGMENTS

In addition to color, important pigment characteristics are brightness, tinting strength, lightfastness, bleed resistance, and opacity. Tinting strength is the ability to color a white base. Lightfastness is the pigment's resistance to fading or color change from prolonged light exposure, especially UV. Bleed resistance is important when a topcoat is applied over a base coat. Some pigments in the base coat may bleed into the applied coat if they are soluble in the topcoat's solvents. Opacity, or hiding power, is a property of particular interest with white pigments such as TiO_2 . It is the pigment's ability in a dried film to obscure any color from the substrate.

A pigment's particle size and refractive index determine its degree of opacity—the smaller the particles, the greater the number of interfaces between the dispersed pigment and binder. This increases light scattering until the particle diameters are about half the wavelength of light, 0.2 to 0.4 μm . With even smaller particles, scattering power diminishes because light simply goes around them. Opacity is also proportional to the difference in refractive index between the binder and pigment. A greater difference results in a higher degree of light scattering and thus greater opacity. Flat paints have greater hiding power than high-gloss paints because they are typically so highly loaded with pigment that the pigment particles partially interface with the air. Because air has a very low refractive index, higher opacity is the result.

Chemical reactivity can also be an important consideration in pigment selection. Some pigments, for example, can react with air pollutants, causing discoloration. Different pigments can even appear to have exactly the same shade of color under indoor lighting but show differences in color in outdoor light. This phenomenon,

called *metamerism*, is caused by differing spectrophotometric absorption characteristics between the pigments.

There are two broad classes of paint pigments, organic and inorganic. In most cases, there will be several organic and inorganic pigments for the same color group.

White Pigments

The primary white pigment in coatings is TiO_2 , which is available with an average particle size close to half the wavelength of light, the optimal for light scattering. It has a relatively high refractive index (2.5 for anatase and 2.7 for the rutile crystallographic form) and is chemically inert. Titanium dioxide is the best general-purpose white pigment for hiding power.

Other white pigments are used, but all have shortcomings compared to TiO_2 . Zinc oxide can be chemically reactive with the binder resin and is not as cost-effective for hiding. Lithopone (barium sulfate/zinc sulfide) is generally too costly for high-volume use. White minerals such as talc and calcium carbonate are not effective compared to TiO_2 mainly because of insufficiently high refractive index.

Black Pigments

Carbon black is the most common black pigment in coatings, although it is one of the most difficult to adequately disperse. Carbon blacks are insoluble in all solvents but do have some affinity for aromatics. They have very high tinting strength and opacity. Three types of carbon blacks are available to the paint industry. Furnace blacks are the most commonly used and provide medium jetness (black intensity). Thermal blacks have larger particle size, are more expensive, and display a lower degree of jetness. Channel blacks provide the highest degree of jetness and are still used in paints even though they must be imported. Black iron oxides are available in a range of jetness and are preferred to carbon blacks in certain applications because of their lower oil absorption and relative ease of dispersion.

Colored Pigments

The inorganic colored pigments are generally less expensive and more widely used than their organic counterparts. The inorganics provide excellent heat stability and lightfastness but are more difficult to keep uniformly suspended because of their relatively high specific gravity. Many of the inorganic pigments are based on lead, chromium, and cadmium, and their use is limited by toxicity concerns. Some representative inorganic pigment types are

- Red (iron oxide): Fe_2O_3
- Yellow (hydrated iron oxide): $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$
- Yellow (lead chromate): PbCrO_4
- Yellow (cadmium sulfide): CdS
- Green (chromium oxide): Cr_2O_3
- Blue (iron blue): $\text{Fe}(\text{NH}_4)\text{Fe}(\text{CN})_6$
- Blue (ultramarine blue): $\text{Na}_6\text{Al}_6\text{Si}_6\text{O}_{24}\text{S}_4$
- Orange (chrome orange): $\text{PbCrO}_4 \cdot \text{PbO}$
- Orange (molybdate orange) $\text{PbCrO}_4 \cdot \text{PbMoO}_4 \cdot \text{PbSO}_4$

A spectrum of hues is obtained through hydration, coprecipitation, and blending of inorganic pigment compounds in various proportions.

Organic pigments are generally purer, brighter, and higher in tinting strength than the inorganics. The chemical nature of some organic pigments, however, makes them sensitive to heat, solvents, or pH extremes. Many organic structures absorb electromagnetic radiation in the UV portion of the spectrum but not in the lower

energy visible portion. Thus the vast majority of organic compounds are clear white powders. To obtain a selective absorption in a portion of the visible spectrum, conjugated organic structures consisting of fused aromatic rings, chromophore groups, or organo-metallic complexes are used. The organic pigments are categorized according to distinct chemical types as monoazo pigments, diazo pigments, phthalocyanine pigments, quinacridone pigments, acid dye pigments, basic dye pigments, and miscellaneous polycyclic pigments.

Metallic and Nacreous Pigments

Metal flake pigments are made from aluminum, stainless steel, and bronze. The most widely used are those of aluminum, made by milling a mineral spirits suspension of finely divided aluminum metal with a steel ball mill. The resulting thin flakes are produced in a variety of particle sizes. Aluminum flakes for coatings are produced as leafing and nonleafing. Leafing flakes are surface treated, usually with stearic acid, to minimize surface tension. This provides flake orientation at the surface of the coating film. The continuous overlapping of aluminum flakes acts as a barrier to oxygen and water vapor while providing a bright metallic appearance. Leafing aluminum flake is used in corrosion-resistant paints for steel structures and in roof coatings to improve weatherability and decrease heat absorption. Nonleafing aluminum flake is not coated and is formulated to be encapsulated within the binder film, but parallel to its surface. It is used most commonly with transparent color pigments in automotive topcoats to provide a metallic color that changes shade with the angle of viewing.

Nacreous (pearlescent) pigments are thin, transparent platelets of high refractive index that partially transmit and partially reflect light. The pearlescent effect results from specular reflection from the broad surfaces of the transparent platelets and the parallel orientation of those platelets at various depths within the binder film. Light transmitted through platelets near the film surface is partially reflected by deeper platelets. The dependence of reflection on viewing angle and the sense of depth created by reflection from many layers produce the pearly luster.

The first pearlescent pigment was derived from fish scales as platy crystals of guanine and hypoxanthine. This remained unrivaled in luster for approximately 300 years, until the refinement of crystallization processes for platy basic lead carbonate in the 1950s. Bismuth oxychloride was developed as a nontoxic alternative to lead carbonate, but the most widely used nacreous pigments in coatings today are the coated micas.

White nacreous pigments are made by forming a uniform coating of TiO_2 on mica platelets. The mica serves as a transparent template so that the high refractive index TiO_2 can assume the required platy shape. Pearlescence is optimized when the pigment optical thickness (platelet thickness \times refractive index) is in the 100-nm (blue white) to 140-nm (yellow white) range. Thicker platelets are produced to make interference colors. Light interference is created by interaction of the reflections from the upper and lower surfaces of the platelet. A reflection maximum occurs at the wavelength of light for which these two reflections are in phase. A reflection minimum occurs at the wavelength for which they are exactly out of phase and cancel each other. A transparent, colorless nacreous pigment platelet acts as a filter, separating light into two components: the reflected color and the complementary transmission color.

When coated on a white surface, the nacreous pigment provides a two-tone metallic effect. The reflected color (specular) is seen as a highlight. The background color at nonspecular angles is created by the diffuse reflection (from the white surface) of the transmission color. The complementary reflection/transmission

colors as a function of pigment optical thickness range in a continuous spectrum from blue-white at 100 nm, to magenta/green at 250 nm, to green/red at 370 nm.

The color effects of nacreous pigments are supplemented by overcoating the TiO_2 -mica platelets with a thin, transparent film of a light-absorbing colorant, for example, iron oxide for yellow, ferric ferrocyanide for blue, chromium oxide for green, and carmine for red. The combination pigments thus produced can have matched reflectance and absorption color, or these can be two different colors. When the colors are the same, the same color is seen at all viewing angles, with metallic highlights provided at specular angles. With different colors, a two-color effect is achieved. Combination interference/absorption pigments are made in the gold-to-red range by coating Fe_2O_3 directly onto mica.

The TiO_2 -coated and Fe_2O_3 -coated micas are used to provide metallic, two-tone, and two-color effects in industrial and automotive coatings. They are widely used in the latter with surface treatments designed to improve dispersability and weatherability.

BINDERS

Binders are the polymeric components in a coating formulation that form the protective film. The binder literally bonds the pigment particles together in the film. If the coating contains no pigments or extenders, then the binder will usually form a glossy transparent or translucent coating.

Drying Oils

Drying oils are vegetable or fish oils and chemically are triglycerides based on a blend of saturated, unsaturated, and polyunsaturated fatty acids. They form flexible films through oxidative cross-links between the polyunsaturated fatty acid groups of different triglyceride molecules. Linseed oil, tung oil, and fish oil are commonly used drying oils. Linseed oil, from flaxseed, was once widely used by the paint industry. More than 50% of its fatty acid component is triunsaturated linolenic acid. The high linolenic acid content tends to cause some yellowing, but in highly pigmented paints this is usually not a problem. Tung oil, from the nut of the tung tree, is 80% eleostearic acid. Because of this acid's conjugated, triple unsaturation, tung oil is faster drying than linseed oil, giving good film hardness and flexibility. Fish oil contains high levels of both reactive and nonreactive acids. It can impart an undesirable odor, and it dries more slowly than linseed oil and gives a softer film because of the plasticizing, saturated, nonreactive fatty acids present. Paints based solely on drying oils have been substantially replaced by alkyds, acrylics, and other synthetic polymers. Drying oils provide a softer film than synthetic binders, have a low gloss, and are used only in highly pigmented paints. These paints have relatively poor durability and chemical resistance, and today they are used in small volumes for limited applications.

Oleoresinous Binders

Oleoresinous binders are used principally in making varnishes. They are produced by "cooking" a resin with a natural drying oil, usually tung or linseed oil. This process dimerizes and oligomerizes the oil and renders the oil and resin mutually compatible and soluble in a thinning solvent. The ratio of oil to resin determines many of the final film properties. A higher ratio of oil to resin gives a slower drying speed, greater softness, increased flexibility, and reduced gloss. With a lower ratio of oil to resin, there is an increase in drying speed, high film hardness, and increased gloss. The ratio of oil to resin is commonly referred to in the varnish industry as oil length, which is defined as the number of gallons of oil to 100 pounds of resin, as follows:

Varnish Type	Oil Length
Short oil	5–15
Medium oil	16–30
Long oil	>30

The resins used in making oleoresinous varnishes include polyterpene resins, petroleum resins, coumaron e-indene resins, gum rosins, wood rosins, tall oil rosins, rosin soaps, rosin ester s, novolac phenolic resins, and rosin-modified phenolic resins. Most oleoresinous varnishes are made from gum, wood, and tall oil rosin esters or soaps and phenolic resins. In clear coatings, oleoresinous binders have been largely replaced by polyurethanes, which have superior hardness, chemical resistance, and water resistance.

Alkyd Resins

Alkyd resins are produced by the reaction of a dibasic acid with a polyol and a fatty acid. A common example of alkyd resin formation is the polycondensation of glycerin, phthalic anhydride, and monocarboxylic fatty acid. The resulting polymer is soluble in aliphatic solvents if the content of fatty acid is sufficiently high. Although fatty acids can be used directly, less expensive vegetable or fish oils are usually used. Many alkyd resins are available because of the wide variety of possible reactants. After glycerin, pentaerythritol is the most commonly used polyol because it improves water resistance, raises viscosity, increases film hardness, and accelerates drying of the alkyd. Because it is tetrafunctional and very reactive, it is commonly used with other polyols such as glycerin or ethylene glycol. Sorbitol, trimethylolpropane, diethylene glycol, and propylene glycol are also used in alkyd synthesis, depending on the particular resin properties desired.

Phthalic anhydride is the most common dibasic acid for producing alkyd resins. Alkyds based on isophthalic and terephthalic acid are often used in exterior coatings where improved hydrolytic stability is required. Maleic anhydride is used with other polybasic acids as a modifier to increase alkyd viscosity and film hardness. Trimellitic anhydride is used in making water-soluble alkyds for specific applications. Soybean oil is commonly used to produce nonyellowing alkyds. When discoloration is less important, linseed oil or tung oil are used for faster drying. Sometimes a nondrying oil such as cottonseed or coconut is used when the alkyd resin is to serve as a plasticizer rather than a film former.

Oil length also affects alkyd properties. The solubility of short oil alkyds is limited to aromatic solvents and other nonaliphatic solvents. They are baked to form a film and are generally restricted to industrial coatings. Long oil alkyds are readily soluble in aliphatic solvents and are air dried. They are easily applied by brush and are used extensively in architectural coatings. Generally, as oil length increases, viscosity decreases, hardness decreases, flexibility increases, and water resistance is reduced.

Alkyd chemistry lends itself to even further modification. Vinyl-modified alkyds, for example, are produced for more durable and quicker drying films, although with some sacrifice in cross-linking rate and consequent development of solvent resistance. Acrylics, silicones, phenolic resins, and natural resins are likewise used to tailor film gloss, flexibility, durability, and drying time for certain applications.

The ability of alkyds to be modified in so many ways accounts for their use in more types of paints than any other binder. Versatility is their primary advantage. A noted disadvantage is the lack of the alkyd film's chemical resistance. Alkyds, being modified polyesters, do not possess high alkali resistance and are subject to attack by hydrolysis. Conventional alkyds are also dependent on the use of organic solvents.

Solvent emissions are minimized with water-reducible alkyds. The simplest approach has been to emulsify the alkyd, although alkyd emulsion paints do not compete with synthetic latex paints in cost or performance. A more effective approach has been to attach carboxylate groups to the alkyd molecule. Such water-reducible alkyds are made by using low-molecular-weight styrene-allyl alcohol polymers as the polyol. These alkyds are maleated by reaction with maleic anhydride and then hydrolyzed to carboxylate salt groups with amine and water. The resulting maleated alkyds form stable aqueous dispersions. After the coating is applied, the volatiles, including a mine, evaporate and the film cross-links by auto-oxidation. The carboxylic acid groups remaining in the cross-linked film, however, generally provide inferior water and alkali resistance compared to the corresponding nonmaleated, solvent-borne alkyd.

Acrylics

Acrylic binders are widely used in both solvent coatings and latex paints for their inherent clarity, color stability, and resistance to yellowing. Of the thermoplastic acrylics, poly(methyl methacrylate) is the largest volume used. Alkyl groups can include methyl, butyl, isobutyl, 2-ethylhexyl, isodecyl, and lauryl. A combination of methacrylates and acrylates is sometimes used to balance film properties. For example, poly(methyl methacrylate) provides film strength and hardness whereas poly(methyl acrylate) improves film flexibility. A plasticizing monomer such as ethyl acrylate or ethylhexyl acrylate is therefore added with the methyl methacrylate monomer by the polymer manufacturer in an addition-polymerization process to produce a copolymer for use in coating formulations. The softer and more flexible polymer facilitates latex film formation.

Thermosetting acrylics incorporate functional carboxyl, hydroxyl, or amide groups. Acrylamide and acrylic acid are often used as functional monomers for this purpose. The thermosetting acrylics are formulated with other reactive resins, such as epoxies, to provide a thermally cross-linked film. These films are considerably harder, tougher, and more chemically resistant than those obtained from thermoplastic acrylics.

Acrylic latex paints dominate the trade sales market for both exterior and interior use because of their balance of film adhesion, durability, flexibility, color stability, alkali resistance, and ability to withstand blistering and chalking. Thermoplastic acrylic solvent-borne paints are used in high-volume applications like automotive finishes, whereas thermoset acrylics are used to bake a hard enamel finish onto large appliances.

Vinyl Resins

In the coatings industry, vinyl resins usually refer to either polyvinyl chloride or polyvinyl acetate (PVAc), which is widely used in interior latex paints. PVAc homopolymer is too hard to allow its colloidal latex particles to coalesce well at ambient temperatures, so most PVAc emulsions used in the paint industry are actually copolymers with a plasticizing monomer such as dibutyl maleate, 2-ethylhexyl acrylate, *n*-butyl acrylate, dibutyl fumarate, isodecyl acrylate, or ethyl acrylate. Copolymers of vinyl acetate and ethylene are also produced for latex paints. External plasticizers are used as well. All of these modifications soften the polymer to facilitate coalescence of the latex particles into a continuous film. PVAc emulsions are less expensive than acrylic emulsions but impart very good color stability and durability. This has enabled PVAc to penetrate a large portion of the interior house paint market.

As a halogenated polymer, polyvinyl chloride is used in specific coatings to provide low moisture permeability films. The major use of polyvinyl chloride, usually as a vinyl acetate copolymer, is in coatings where corrosion protection is a major function. Polyvinyl

chloride copolymers with high vinyl chloride content are used in thermoplastic powder coatings. They are limited in this application by the deficiencies common to thermoplastic binders: they are difficult to pulverize to small particle size, their high molecular weight gives high-melt viscosity and consequent poor flow and leveling, and they are restricted to applications that can accommodate a relatively thick coating.

Styrene-Butadiene Binders

Homopolymers of styrene are too hard to form a continuous film from a latex, but a plasticizing monomer can be copolymerized to produce a softer polymer. A ratio of two parts styrene to one part butadiene is commonly used to produce the styrene-butadiene latexes used in coatings. This is nearly the inverse ratio used to produce styrene-butadiene rubber (SBR). Styrene-butadiene latexes were the first practical latexes to be used in interior architectural applications in the 1950s, but they are not commonly used today. One advantage of styrene-butadiene emulsion paints is superior alkali and chemical resistance, which is greater than either PVAc or acrylic emulsion paints. A major disadvantage is the susceptibility to oxidation because of the unsaturation in the butadiene units of the polymer backbone. This oxidation leads to yellowing and ultimately film embrittlement.

Polyurethane Resins

Many solvent-borne finishes are based on polyurethane resins because they are characteristic ally tough yet flexible, and very resistant to abrasion. They also impart good film adhesion and can be made to harden at ambient temperatures. In the coating industry, any polymer containing the urethane linkage in the backbone, even if that same polymer may also contain many other linkages, is called a polyurethane. Generally, the polyurethane resins involve the reaction of a diisocyanate with a hydroxyl compound. Polyurethane coatings are used as a single-pack system or a two-pack system. There are three basic types of single-pack systems and two of the two-pack systems. More recently, waterborne urethanes have been developed to reduce solvent emissions.

Oil Modified

Oil-modified finishes are based on a polyurethane-modified alkyd. These are also called polyurethane-alkyds or simply uralkyds, and are prepared in a manner similar to alkyds, with a diisocyanate, usually toluene diisocyanate (TDI), replacing the polycarboxylic acid. Thus, the reaction product possesses urethane linkages instead of the ester linkages associated with traditional alkyds. The percent isocyanate, or conversely oil length, determines the properties of the resulting film. Higher isocyanate content (shorter oil length) reduces film flexibility and impact resistance, increases film hardness and solvent resistance, and reduces drying time. In certain commercial coatings, some of the isocyanate is replaced by phthalic anhydride to make phthalic-modified uralkyd. Uralkyds are cured through oxidative drying in the same manner as regular alkyds. Metallic driers can likewise be used to accelerate drying. Uralkyds are one of the most commonly used polyurethane resins, finding particular application in varnishes for floors, boats, and general use. Although these resins do not impart the best gloss, they do give excellent abrasion resistance and generally better water and alkali resistance than an alkyd.

Moisture-Curing Prepolymers

Moisture-curing prepolymers are single-pack polyurethane systems that cure from exposure to atmospheric moisture. Initially a diisocyanate such as TDI is reacted with a high-molecular-weight polyol

such as castor oil. The TDI reacts with a minimum of three hydroxyl groups per molecule to produce a trifunctional prepolymer. After application, the prepolymer is cured into a hard film from exposure to moisture in the air. Two isocyanate groups, in the presence of water, bond to form a urea. Cure rate is greatly dependent on relative humidity, and care must be taken that all pigments and mineral additives are free of moisture to avoid reaction before use. This system results in a tough film and is commonly used in floor coatings.

Blocked Isocyanates

In the blocked isocyanate system, polyol is reacted with a diisocyanate such as TDI to form a structure with isocyanate adducts. These adducts are then reacted with a blocking agent, usually phenol. The bond between the phenol and isocyanate is stable up to 150°C, so no reaction will take place while the coating is stored. After the coating is applied, it is baked, causing the phenol to split off and allowing the resin to cross-link.

Catalyzed Moisture Cures

Catalyzed moisture cure is a two-component system that is the same as the one-package moisture cure system except that a tertiary amine catalyst such as *N,N*-dimethylethanolamine is added just before application. This shortens cure time and increases the cross-link density of the film for better chemical resistance. As soon as the catalyst is added, there is limited pot life before gelation occurs.

Two-Pack Systems

In two-pack systems, one package contains a low volatility isocyanate, usually a polyisocyanurate (a polymerized TDI), and the other consists of the polyol component, which may be either a polyether or saturated polyester resin. The distance between the hydroxyl groups on the polyol relates to resultant film flexibility and hardness. If film flexibility for greater exterior durability is required, sufficient space between these hydroxyl groups is needed. If a high cross-link density is required for greater film hardness, the distance between these reactive hydroxyl groups is less. When the two packages are mixed, the isocyanate functional groups react with the polyol hydroxyls. It is also possible for atmospheric moisture to enter into the reaction, resulting in urea cross-links. Two-pack systems have a short drying time and are often used for coating floors, furniture, boats, metals, and concrete.

Water-Reducible Urethanes

One approach to incorporating polyurethane coating attributes into aqueous vehicles has been to prepare a hydroxyl-terminated polyurethane with 2,2-dimethylolpropionic acid as one of the diols. The carboxylic acid group is sufficiently sterically hindered to minimize amide formation, so that a polyurethane is formed with pendant acid groups. These are neutralized with amine and diluted with water to form a stable polyurethane dispersion. In use they are cross-linked with methylated monomeric melamine-formaldehyde (MF) resins. Another approach is to first prepare an isocyanate-terminated polyurethane in acetone. This is the ncha in-extended with a sulfonate-substituted diamine. The acetone solution is diluted with water, and then the acetone is removed by distillation, leaving an aqueous polyurethane dispersion stabilized by charge repulsion of sulfonate groups.

Epoxy Resins

The coatings industry uses approximately half of all the epoxy resins produced in the United States. Although epoxy coatings provide superior chemical resistance, high film adhesion strength, and tough

but flexible films, they are relatively expensive and slow to harden, with relatively poor gloss retention and UV resistance. The coatings industry has used many different types of epoxy resins. The most common are those produced from the reaction of bisphenol-A with epichlorohydrin. These are used in two-pack systems with amines, polyamines, polyamides, or acid anhydrides. Amine combines with an epoxy group in a ring-opening reaction, so the reaction of a trifunctional amine and diepoxide results in a three-dimensional cross-linked matrix. This forms the basis of industrial maintenance coatings and marine coatings, among others, with exceptional resistance to solvent and chemical attack.

Solvent and chemical resistance is even further improved by blending the epoxy with a phenolic resin and baking the coating. At elevated temperatures, the phenolic resin and epoxy groups react through a ring-opening mechanism. The secondary hydroxyl groups react further to form a tight, cross-linked network that imparts optimum solvent and chemical resistance. Flexibility of the film is reduced, however, compared to other epoxies, and discoloration can be a problem. If a lighter color is needed, urea-formaldehyde resins are reacted with the epoxy with little loss in chemical and solvent resistance.

Epoxy resin esters are formed by reacting an epoxy resin with fatty acids from drying oils. The fatty acids react with both the epoxide and hydroxyl groups of the epoxy resin to form the epoxy ester. Epoxy resin esters are less expensive than other epoxies because they are partially composed of lower cost fatty acid. They also have superior flexibility, but poorer solvent and chemical resistance, although generally better chemical and alkali resistance and better adhesion than conventional alkyds. As with alkyds, they are usually cured by auto-oxidative air drying with the aid of metallic driers. These resins are used in industrial and maintenance paints, automotive primers, and varnishes.

Amino Resins

Amino resins are rarely used as the sole binder in coatings because they form hard, brittle films with only fair adhesion. They are, however, the predominant cross-linking agents for thermosetting coatings. MF resins are most commonly used for these applications. Amino resins are prepared, in general, by reacting precursor and formaldehyde under alkaline conditions to form methylol groups. Alcohols are then reacted under acid conditions to yield ethers.

MF resins are most often used to cross-link resins having hydroxyl functionality such as alkyds, thermoset acrylics, hydroxy-terminated polyesters, and bisphenol-A epoxy resins. Cross-linking is through transesterification using an acid catalyst. MF resins will also cross-link carboxylic acid functional resins through esterification, although the reaction rate is slower than with hydroxyl groups. This is significant in the formation of water-based coatings based on hydroxy-functional binders that have been modified with carboxylic acid groups to improve dispersibility. The curing system for these binders is chosen to ensure a high degree of esterification, so that residual carboxylic acid groups do not increase the water sensitivity of the cured film. MF resins are also increasingly used with binders having both hydroxyl and urethane functionality.

Amino resin analogues to the MF types are produced from glycoluril, acrylamide, and methacrylamide, which provides greater film flexibility, and benzoguanamine, which provides greater alkali resistance, but the next most widely used are urea-formaldehyde (UF) resins. UF resins are generally the least expensive of the amino resins. They are also the most reactive. Coatings with UF resins can therefore be formulated for ambient or low-heat cures, but the

resulting films have relatively poor hydrolytic stability. Although the other amino resins are used in metal coatings, UF resins are used in coatings for temperature-sensitive substrates such as wood finishes, where corrosion resistance is unimportant.

Cellulosic Binders

The solvent-soluble cellulose esters, nitrocellulose and cellulose acetobutyrate, are used in coatings. Nitrocellulose is made by reacting cellulose with nitric acid. Cellulose hydrolysis and consequent molecular-weight reduction are a function of the small amounts of water present during the reaction. Greater hydrolysis results in lower molecular weight, lower solution viscosity, and lower film strength. The degree of nitration determines solvent compatibility. Polymers containing approximately 11% nitrogen are alcohol soluble and used in flexographic printing inks. Coatings grades contain about 12% nitrogen and are soluble in esters and ketones and in mixtures of esters and ketones with alcohols and hydrocarbons. Explosive grades contain about 13% nitrogen. Nitrocellulose lacquers provide thermoplastic films with high gloss and easy repairability but low durability. They were used for automotive finishes before acrylic lacquers were developed but today are used in wood finishing. The principal use of cellulose acetobutyrate has been as a component of acrylic-based metallic automotive finishes. The cellulosic component contributes to flow control and the orientation of aluminum flake pigment parallel to the film surface for maximum metallic effect.

SOLVENTS

Coatings solvents can be classified by function as active, latent, or diluent. An active solvent dissolves the binder. A latent solvent does not itself dissolve the binder but acts as a cosolvent when used with an active solvent. A diluent solvent has no solvency for the resin but is used to dilute the active solvent without precipitating the binder. Diluent solvents are used to reduce coating viscosity and cost. For each coating, solvent selection is guided by the required balance of solvency and evaporation rate. The solvent or solvent blend must keep the binder in solution throughout the drying process to optimize subsequent film properties. The evaporation rate must be appropriate for the application method, spraying versus brushing, for example; it must be initially relatively quick to avoid sag and then more controlled to allow proper leveling and adhesion. Coatings solvents are also classified according to chemical nature as hydrocarbons, oxygenated solvents, and "other," which are usually hydrocarbon derivatives.

Hydrocarbon Solvents

Hydrocarbons are the most widely used solvents and are typically subdivided as principally aliphatic, naphthenic, or aromatic. The most commonly used of these are aliphatic solvents, containing mainly iso- and normal paraffins. Some aliphatics contain naphthenes (cycloparaffins) and aromatics, which improve solvation power but increase odor. Mineral spirits is the primary aliphatic solvent, with several grades available based on evaporation rate and solvency. Low-odor grades contain mostly isoparaffins, although a lack of naphthenes and aromatics reduces solvency with many resins. Mineral spirits are widely used in architectural paints because their balance of moderate solvency and moderately slow evaporation impart good brushability, leveling, and wet edge. Varnish maker's and painter's (VM&P) naphthas are similar in solvency but evaporate much more quickly. They are used primarily in sprayed coatings.

The aromatic solvents provide stronger solvency but greater odor. The most common are toluene, mixed isomer xylenes, and

two high-flash-point aromatic naphthas. The fast-evaporating toluene is used in spray paints and industrial coatings. The mixed xylenes, with moderate evaporation rate, are used in industrial coatings, whereas the slow-evaporating aromatic naphthas are used in baked finishes.

Terpenes, unsaturated cyclic hydrocarbons from pine trees, represent the historically oldest coating solvents, although they are infrequently used today. Turpentine is the most common terpene solvent, although dipentene, with stronger solvency and slower evaporation, is also used. Turpentine offers greater solvency, although in a narrower range, faster evaporation rate, greater odor, and higher cost than mineral spirits, which has widely replaced it.

Oxygenated Solvents

The principal oxygenated solvents for coatings are ketones, esters, glycol ethers, and alcohols. These are high-purity synthetic compounds that provide much stronger solvency than hydrocarbon solvents and partial to complete water miscibility. They are widely used as active solvents for synthetic binders because they can be blended to provide tailored solvency and evaporation rate.

The ketones are characterized by their strong odor and range of evaporation rate and water solubility. The very volatile acetone is used in sprayed coatings, particularly nitrocellulose and acrylic lacquers, to reduce viscosity and then flash off during application. The fast-evaporating methylethylketone and moderately evaporating methylisobutylketone are widely used as active solvents in paints and lacquers based on synthetic binders, whereas the very slow evaporating isophorone is used in baked industrial coatings.

The esters provide solvency nearly equal that of ketones but with a more pleasant odor. The most common are the alkyl acetates, ranging from the very rapidly evaporating methyl acetate to the slowly evaporating hexyl acetate. One of the most widely used ester solvents, *n*-butyl acetate, has a medium evaporation rate and is used as a standard reference for expressing the evaporation rate of other solvents. In comparison to its assigned evaporation rate of 100, acetone has an evaporation rate of 1,160 and regular mineral spirits has an evaporation rate of 10. Glycol ether acetates are relatively slow to evaporate and are used as coalescents in latex paints and retarder solvents in solvent coatings. In the latter capacity, they maintain flow and leveling after the other solvents have evaporated.

Glycol ethers provide both alcohol and ether functionality and are characterized by mild odor, water miscibility, strong solvency, and slow evaporation. Ethylene glycol ethers have been widely used in water-based coatings as coupling solvents for water-reducible binders, and at low levels in lacquers as retarder solvents. More recently, propylene glycol ethers have replaced ethylene glycol ethers in many applications because of health and safety considerations.

Alcohols are used at low levels in waterborne paints as coupling solvents with glycol ethers and in certain solvent coatings as latent solvents. Denatured ethanol and *n*-butanol are the most commonly used, with the former also serving as an active solvent for shellac, PVAc, and several phenolics.

Organic carbonates and furan derivatives are specialty oxygenated solvents. Ethylene carbonate and propylene carbonate are cyclic esters with good solvency, very slow evaporation, and very low odor. Tetrahydrofuran, furfuryl alcohol, and tetrahydrofurfuryl alcohol are cyclic ethers with particularly strong solvency for vinyl polymers and certain other synthetic binders.

Other Solvents

N-methyl-2-pyrrolidone is a specialty solvent used in waterborne paints. It offers strong solvency, water solubility, biodegradability,

slow evaporation, and low toxicity. 1,1,1-trichloroethane is used as a fast-evaporating solvent in some spray coatings because it is not photochemically reactive and is thus not included in volatile organic compound (VOC) content, although health and environmental concerns over chlorinated solvents have restricted its use. Supercritical carbon dioxide is used as a diluent solvent in airless spray coating operations because of its high solubility in most formulations, low toxicity, low cost, viscosity-reducing effect, and behavior on application as a highly volatile solvent.

ADDITIVES

The chemical and mineral additives are typically used at less than 5% by weight, usually much less, to optimize coatings properties before, during, and after cure. Even with their relatively low concentration, they have a considerable effect on paint properties.

Dispersants and Surfactants

The dispersants commonly used in waterborne coatings include potassium tripolyphosphate, and sodium or ammonium salts of lignosulfonates, polynaphthalene sulfonates, and relatively short chain polyacrylates and polymethacrylates. These chemicals have little effect on surface tension or interfacial tension but align themselves so that their organic groups loosely attach to and coat the pigment and mineral surfaces, leaving their charged groups protruding into the water. This charged film renders the particles mutually repulsive, which retards settling and minimizes the viscosity contribution of particle-particle associations. Dispersants are therefore used to improve suspension stability and enable the inclusion of more pigment and extender without compromising rheological properties.

Surfactants reduce surface tension so that the liquid vehicle can effectively wet the pigment and extender surfaces. This is a particular requirement for hydrophobic solids such as talc. Surfactants also facilitate the application of coatings by allowing the paint to better wet and spread on the substrate. Anionic surfactants are typically sodium salts of alkyl sulfates, alkyl sulfonates, alkylaryl sulfonates, and sulfosuccinates. They often serve simultaneously as dispersants, although it is not uncommon for a paint to contain both surfactants and dispersants for optimum effect. Nonionic surfactants such as nonylphenol ethoxylates contain a pigment/mineral compatible group, a long chain alkyl or alkylaryl group, and a hydrophilic group such as polyethylene oxide. The long chains bond loosely to the pigment and extender surfaces, creating a film of hydrophilic groups that ensures wetting by the aqueous vehicle. Nonionic surfactants can also provide a dispersant effect by providing steric hindrance to particle flocculation.

Dispersion aids for solvent-borne paints function primarily as wetting agents and are typically nonionic. They contain an anchor group, selected for its affinity to the particulates in the paint formulation, and a polymeric or high-molecular-weight group selected for its compatibility with the binder and solvent.

The surfactants used to stabilize binder lattices in latex paints are properly considered emulsifying agents, with an organophilic component that is at least partially soluble in the binder droplets and a hydrophilic component that allows the droplet to be wet by the aqueous vehicle. Emulsifying agents can be either anionic or nonionic and inhibit droplet coalescence by charge repulsion or steric hindrance.

Rheology Modifiers

Adjusting paint rheology for optimal in-can stability and application properties requires the use of thickeners, thixotropes, and rheology modifiers of various types. Liquid paints for brush, roller, or

spray application are pseudoplastic (shear-thinning). Paint viscosity decreases as the shearing rate increases. Undisturbed in the can, high viscosity inhibits settling and flocculation of pigments and minerals. The shear caused by brushing or spraying reduces the viscosity so that a thin film is easily applied. Once on the substrate, the paint rethickens so that sagging is avoided. Pseudoplasticity, however, implies an immediate recovery of viscosity after shearing stops. This is not always desirable because rapid viscosity recovery impedes leveling and retains brush marks, roller marks, or orange peel. The proper balance of antisag and good leveling is usually attained by using cellulosic thickeners and mineral thixotropes, which impart the desired degree of thixotropy to the paint. A thixotropic paint is shear-thinning, for easy application and good coverage; but after shear is removed, viscosity recovers over a short period of time. When properly formulated, this provides just enough time for the paint film to level while developing enough viscosity to prevent sagging.

Roller application involves an additional consideration—control of spattering. At the point of contact between roller and substrate, the paint is under pressure. As the roller moves, the pressure is released and small bubbles are formed between the substrate and the receding roller edge. As the roller continues, the bubbles expand and their walls are stretched from roller to substrate until they resemble fibers. These paint “fibers” are eventually stretched to their breaking point. Ideally, part of the fiber retracts into the substrate coating and the rest onto the roller. In reality, the fiber generally breaks in two places, releasing free paint droplets that fly off as spatter.

Spattering is a particular problem with latex paints that contain conventional water-soluble, high-molecular-weight thickeners. Paint fibers stretching between roller and substrate experience elongation flow rather than shear flow. The corresponding elongation viscosity arises from the stretching and aligning of the thickener polymer chains. The long-chain, high-viscosity polymers impart the high elongation viscosity that promotes spatter. Spattering is minimized by the use of low-molecular-weight (short-chain) grades of these thickeners, but at the expense of shear viscosity.

Adequate low-shear viscosity is required to promote product uniformity. High-shear viscosity is an important factor with regard to spreading rate and hiding. The most widely used conventional thickeners are very shear-thinning, so that very thin paint films can be applied. If the applied film is too thin, however, the dried film will give poor hiding. One-coat paints require a relatively elevated high-shear viscosity so that an optimally thick wet paint film is applied. In paints using conventional polymeric thickeners, a balance among viscosity, wet film build, spatter resistance, sag resistance, and leveling is often achieved by using intermediate viscosity polymers and mineral thixotropes.

Conventional Thickeners

The most commonly used thickeners in waterborne coatings are the naturally derived nonionic celluloses. Medium- and high-viscosity hydroxyethylcelluloses dominate this group. Hydroxypropylmethylcellulose is the only other cellulosic with significant use in coatings. The only conventional synthetic thickeners used in substantial amounts in water-based coatings are the acrylic alkali-soluble emulsions (ASEs). These are supplied in liquid form as low-viscosity, water-insoluble latexes at low pH. In use they are neutralized with ammonia or a volatile aminoalcohol to provide thickening. Some are lightly cross-linked with a small amount (<1%) of a polyfunctional monomer to enhance viscosity. The ASEs are similar to the celluloses in rheology, but are more bioreistant and somewhat more water-sensitive.

Mineral Thixotropes

Smectite and hormite clays provide thixotropic aqueous dispersions and impart a controlled degree of thixotropy to paints thickened with the conventional polymers. The most widely used mineral thixotrope in aqueous coatings is the hormite clay palygorskite, which is better known as attapulgite. The micronized attapulgite used in paint is composed of low aspect ratio needles that deagglomerate in water in proportion to the amount of shear applied. When shear is removed, these needles form a loosely cohesive random colloidal lattice that provides suspension and emulsion stabilization. With shear cycling, it is shear-thinning and thixotropic. Because attapulgite deagglomeration is mechanically rather than ionically driven, as for smectite clays, it is insensitive to most solutes and can be added at any point in paint manufacture. Concentrated, predispersed aqueous suspensions of attapulgite are available because optimum deagglomeration and dispersion is energy intensive.

Hydroclassified natural smectite clays and synthetic smectites are used instead of attapulgite in coatings where finer adjustment of rheological properties is required. The hydration and dispersion of a smectite clay into individual colloidal platelets is driven by shear and osmotic swelling. Once separated, the absence of shear allows these platelets to form a more uniform and cohesive structure than that of attapulgite through ionic attraction of slightly positive platelet edges to negatively charged platelet faces. Solute present during hydration can inhibit osmotic swelling, but solutes introduced after hydration can improve the cohesion of the colloidal structure. Despite this relative lack of processing versatility compared to attapulgite, the smectites are used for their higher efficiency and the controllable synergism they provide with polymeric thickeners.

Precipitated silicas find some use as thixotropes in water-based coatings. The functional particles are clusters of strongly agglomerated, primary, amorphous silica particles. Dispersed in a liquid, these clusters are chained together by weak hydrogen bonds into three-dimensional networks. In highly polar liquids, bridging additives ensure this network structure; in aqueous coatings, certain nonionic surfactants serve this function. Silica gels and fumed silicas are used in water-based coatings for flattening rather than rheology control.

Associative Thickeners

Associative thickeners are relatively low-molecular-weight, water-soluble polymers with hydrophobic groups capping polymer and pendant chain ends. These thickeners provide little or no conventional thickening. They instead form a network based on hydrophobe-hydrophobe affinity. Hydrophobe groups associate among the polymer chains, and they adsorb onto hydrophobic surfaces in the dispersed phases of the paint. These surfaces are primarily those of the latex binder but can include hydrophobic pigments and extenders such as talc.

Associative thickeners generally provide solution rheology that is less pseudoplastic than conventional thickeners. This allows greater high-shear viscosity on paint application for optimal film build and hiding, and lower low-shear viscosity for good leveling. Associative thickeners also generally impart lower elongation viscosity, and are therefore preferred for spatter resistance. Hydrophobically modified celluloses, the first commercial associative thickeners, are relatively low-molecular-weight grades of hydroxyethylcellulose and ethylhydroxyethylcellulose modified through backbone hydroxyl groups. Hydrophobe substituents are one or two ethylene oxide units terminated with an alkyl or alkylaryl group. The hydrophobe modification makes these celluloses less pseudoplastic for better film build and leveling.

Among the first acrylic associative thickeners were hydrophobically modified analogues of the ASEs. These are lower in molecular weight than the conventional ASE thickeners, but on neutralization they do provide some viscosity. Subsequently developed ASE-based thickeners have as associative side chains polyethylene oxide segments joined by urethane linkages, with terminal hydrophobe groups. These side chains mimic the structure of the most popular class of associative thickeners, the hydrophobically modified ethoxylate urethane polymers (HEURs).

The HEURs have a backbone and side chains composed of urethane-linked polyethylene oxide segments, terminated at all ends with hydrophobe groups. These products impart the least pseudoplastic rheology and generally provide the best flow, leveling, film build, and spatter resistance. Their use as the sole rheology modifier, however, comes at the expense of sag resistance, suspending ability, and thickening efficiency. The HEURs are pourable aqueous solutions with an organic cosolvent added to suppress viscosity and ensure flowability. In products analogous to the HEUR structure, the polyether segments include ethylene oxide-propylene oxide block copolymer in place of polyethylene oxide, and amide or ether linkages instead of urethane.

Solvent Thickeners

Hydrogenated castor oil is used as a thixotropic thickener in paints based on nonpolar aliphatic solvents. Hydroxyl groups on the fatty acid chains of the castor oil triglyceride form a colloidal network through hydrogen bonds. Polyamide-alkyd resins function as thixotropic thickeners in nonpolar solvents through polar attraction among functional groups.

Precipitated and fumed silicas thicken solvent-borne paints and are most efficient in nonpolar systems. Both can be used in polar solvents, although higher levels are generally required, with fumed silica providing somewhat better efficiency. Organoclays, purified smectite clays that have been cation-exchanged with quaternary ammonium salts, are widely used in solvent-borne coatings. Several grades are available for aromatic or polar solvents and nonpolar solvents, depending on the organic treatment. The conventional organoclays require a polar activator such as methanol or propylene carbonate to facilitate delamination and the formation of a thixotropic colloidal structure through hydrogen bonding. Self-dispersing grades are modified to eliminate the need for a polar activator.

Driers

Paint driers are catalysts for the oxidation and polymerization reactions that provide binder film formation after application. Most driers are soaps of transition metals, providing catalytic activity based on the ability of the metal cation to be oxidized from a stable lower valency to a less-stable higher valency. The organic acids used to form these soaps provide compatibility in solvent-borne paints and enable emulsification into waterborne systems. The earliest driers were linolates, rosinsates, and tallates. These have been mostly replaced by naphthenates and particularly 2-ethylhexanoates. Neodecanoates and so-called synthetic acid (similar to 2-ethylhexanoate) soaps are favored for their higher metal concentration.

Primary driers directly promote oxidative film curing. They catalyze oxygen absorption into the film and accelerate the decomposition of the peroxides that are formed into free radicals that propagate the cross-linking mechanism. The most widely used primary driers are based on cobalt and manganese, and cobalt driers are by far the most reactive. They are surface driers in that they quickly dry the outermost layer of the paint film, preventing further drying—"through drying"—beneath. Cobalt used alone can

consequently result in film wrinkling. Zirconium soaps are used with cobalt driers to retard surface drying, accelerate through drying, and provide harder cured films. Manganese driers are slower than cobalt and provide some through drying, although they are, like cobalt, usually used with secondary driers to properly balance drying properties.

Lead driers used to be the most common secondary drier, their sole function being to catalyze oxygen uptake. This and their relatively low reactivity made them good through driers. Lead toxicity and atmospheric sulfide staining have now all but eliminated their use. Zirconium driers have generally replaced lead; they are not discoloring and are not considered toxic. Aluminum driers are also used in place of lead, but the substitution is not straightforward. The paint must be formulated specifically to promote their activity. Iron driers are used in heat-cured paints where their poor color can be accommodated. Temperatures greater than 100°C are required for catalytic activity, but high film hardness is obtained.

Nonmetallic drier accelerators are commonly used to improve the efficiency of primary driers and to maintain catalytic activity during in-can aging. Metallic soap driers, especially those with cobalt, typically lose some activity between the time of manufacture and use, primarily through pigment adsorption. The heterocyclic compounds 1,10-phenanthroline and 2,2'-diipyridyl form complexes with cobalt and manganese through their nitrogens, acting in effect as chelating agents. The metal-organic complex protects the metal against deactivation through adsorption during storage and modifies the metal's catalytic activity such that through drying is enabled. Proprietary metallic driers are available as another means of preventing the loss of efficiency of cobalt and manganese soaps during paint storage. These "feeder" driers dissolve gradually into the paint vehicle to replace drier metals lost through adsorption.

Coalescing Agents

The dispersed polymer particles in a latex paint must coalesce after application to form a continuous film at room temperature or below. Hard and high glass transition temperature (T_g) polymers must be temporarily plasticized to enable film formation. Coalescing agents serve this function by softening the resin particles and lowering their minimum film formation temperature, but slowly volatilizing after application to allow the polymer film to attain final hardness. Slow-evaporating ester-alcohol solvent is the most common coalescing agent because it efficiently lowers the minimum film-forming temperature of a wide variety of resins, has good hydrolytic stability, and is insoluble in water. The latter is important in preserving coalescent efficiency by preventing loss of solvent from the polymer phase to the aqueous medium. Low-volatility glycol ether ester and glycol ether solvents are also used as coalescing agents.

Plasticizers

Plasticizers are used primarily to improve the flexibility and toughness of the final coating film. They are used more often in industrial, appliance, and automotive coatings than in architectural paints. Plasticizers form strong polar associations with polymer molecules, but because there is no chemical bond, they can be lost through extraction or volatility. Plasticizers are therefore typically very low volatility, water-insoluble liquids that are selected based on compatibility with the resin. The major coatings plasticizers are the phthalic, trimellitic, or adipic acid esters of 2-ethylhexanol or isononanol. The single most commonly used plasticizer is dioctyl (i.e., ethylhexyl) phthalate. The response of dry film properties to plasticizer addition level is not necessarily linear, so in most cases optimal concentration must be determined. In general, increasing the concentration of

plasticizer increases film elongation and permeability and decreases tensile strength. Film toughness and adhesion, however, increase to a maximum and then decrease.

Biocides

Biocides are used in both solvent and aqueous coatings as fungicides and algicides to keep the dried paint film free of discoloring mildew and algae. Biocides are used in waterborne paints as preservatives as well. Here they prevent the bacterial growth that can result in off-gassing in the can, and the enzymatic degradation of cellulosic thickeners that can result in loss of viscosity. Paint biocides are preferably colorless, free of objectionable odors, nonyellowing in the paint film, of low toxicity, environmentally acceptable, and cost-effective. Few, if any, of those in common use today meet all these criteria. Certain biocides are used exclusively as in-can preservatives, others as in-film fungicides, and yet others can serve both purposes. In the last case, the spectrum of biocidal activity is usually related to concentration and solubility. Some biocides, for example, are effective against bacteria at one concentration and effective against fungi at a much higher concentration. Preservatives are usually water-soluble for best effect, whereas in-film fungicides need to have very low water solubility to resist leaching.

In the past, organomercury compounds were the most widely used paint biocides, functioning at very low concentrations as both preservatives and film fungicides. Because of their high toxicity, they have been replaced in most cases by the less toxic but also less cost-effective organotin compounds, particularly tributyltin oxide and zinc oxide. Toxicity and environmental concerns have more recently restricted the use of these tin compounds as well. As the trend in favor of aqueous products continues, the variety of available preservatives has kept pace. These can be generically described as nitrogen or sulfur-containing organic biocides. Many of these are formaldehyde releasers, which largely accounts for their effectiveness but in some cases limits their use.

Broad-spectrum biocides are generally preferred for waterborne paints, but environmental, toxicity, and cost considerations often necessitate tailoring of the biocide system for maximum effectiveness at minimum use levels. This involves identifying the particular types of microorganisms requiring control in both the manufacturing and end-use environments. To avoid development of resistance to a biocide in the manufacturing environment, it is not uncommon for producers to periodically alternate between preservative systems with different biocidal mechanisms.

Antifoams

The surfactants and thickeners used to stabilize water-based paints also stabilize air bubbles entrapped during manufacture or application. Even so, solvent-borne coatings develop bubbles under shear. Bubbles that remain in the applied coating result in cratering in the dried film. Vehicle-insoluble liquids—silicone oils, alkyl (C_6 – C_{10}) alcohols, and mineral oils—are used to destabilize the air bubbles so that they break. In aqueous systems, silicone/amorphous silica combinations are often used. Because antifoams can be emulsified and lose effectiveness on prolonged paint processing, they are sometimes added twice during manufacture—a silicone antifoam during pigment dispersion to prevent air entrapment and a nonsilicone antifoam in the letdown to ensure performance during use.

Glycol

A slow-evaporating glycol is added to latex paints to serve as both antifreeze and humectant. Ethylene glycol is most commonly used, followed by propylene glycol. As water freezes, its volume

expansion can push the latex particles together with sufficient force to cause coagulation. Glycol depresses the freezing point, but even those paints that become cold enough to freeze tend to freeze to a slush that exerts less force on the latex particles. As a humectant, the glycol controls evaporation from the paint film to facilitate wet lapping. When paint is applied by roller or brush, each brushful or rollerful of paint overlaps the wet edge of the preceding area of coverage. Without glycol, evaporation can quickly render the previously applied film edge very viscous, although very weak because of limited latex coalescence. The brush or roller shear from the subsequent application can break up this film, leaving irregularities along the lapped edge.

Antiskinning Agents

The driers used in air-drying paints can also cause oxidative cross-linking at the surface of the paint in its container. This is prevented by adding a small amount of volatile antioxidant such as methylethylketoxime or butyraldoxime. Volatility and use level (<0.2%) are selected so as not to interfere with the drying of the applied paint film, although they may not be adequate to prevent the formation of a skin in a container of paint that has been opened, partially used, and resealed for storage.

Corrosion Inhibitors

Corrosion of metallic surfaces requires moisture, ions, and oxygen. Corrosion inhibitors are most often added to paints to prevent rusting of ferrous metals. Rusting is an oxidative process that occurs through an electrochemical mechanism. For example, a drop of water on steel, which is in effect a conductive electrolyte solution from ambient salts, will create an electrolytic cell. Electrons will flow from the anode at the center of the drop to the cathode at the edge. At the anode, iron is oxidized to Fe^{2+} , and at the cathode, oxygen is reduced to OH^- . The cationic iron migrating toward the cathode and the anionic hydroxyl migrating toward the anode form soluble ferrous hydroxide, $\text{Fe}(\text{OH})_2$. If sufficient oxygen is available, this is oxidized to the insoluble hydrated ferric oxide (rust), $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$.

Coatings can inhibit rusting in proportion to their impermeability to water, oxygen, and electrolyte. Solvent-based coatings provide generally less permeable polymer films than water-based coatings, but none is impermeable. Lamellar metals and minerals are used in coatings to reduce film permeability by physically inhibiting diffusion through the film. Platy minerals such as talc and mica are used for this purpose, although micaceous iron oxide (MIO) and aluminum flake are more widely employed.

Primers containing high levels of zinc dust are used to protect steel by a sacrificial cathodic mechanism. The less noble zinc acts as the electrochemical anode and corrodes instead of the steel substrate. The concentration of zinc powder in the dry primer film must be sufficiently high to allow the particles to make contact and allow an electrical current to be established between these particles and the steel.

Certain inorganic compounds, usually as their zinc salt, are used in paints as passivators to control rust formation. These inhibitors are slightly soluble in water and are slowly dissolved from the paint film through moisture permeability. The ions formed are carried to the film-metal interface by moisture diffusion. There they cause the corrosion electrical potential to be elevated to the passive potential at which the corrosion rate is dramatically reduced by polarization at the anode. Chromates have been the most widely used passivating inhibitors in coatings, although toxicity and carcinogenicity concerns have prompted their replacement by molybdates (zinc and calcium zinc) and zinc phosphate in certain cases. Alkaline

extenders such as wollastonite are used as synergists with passivators in some applications, providing a beneficial pH buffering effect.

Flash Rust Inhibitors

When water-based paints are applied over exposed ferrous metal, the drying film may develop a scatter of light brown spots. This "flash" rusting is prevented with alkaline inhibitors such as sodium nitrite, sodium benzoate, or 2-amino-2-methylpropan-1-ol (AMP). Basic alkaline earth alkylaryl sulfonates are used as both flash rust and corrosion inhibitors. Alkaline minerals, wollastonite in particular, are also used to prevent flash rusting.

Photostabilizers

Many paints are prone to fading and film degradation from exposure to sunlight, particularly UV light. UV absorbers are used to reduce UV absorption by the binder polymer and the resultant photoinitiated oxidative degradation. UV absorbers for exterior coatings ideally have high absorption at 280 nm through 380 nm, with no absorption above 380 nm to avoid color effects. The UV absorber should also be nonvolatile and soluble in the coating film. Hydroxybenzophenones, hydroxybenzotriazoles, and hydroxyphenyltriazines are commonly used, with the last generally providing the lowest volatility and best permanence. Optimum photostability, for example, in clear automotive topcoats, is obtained with synergistic combinations of UV absorbers and hindered amine light stabilizers (HALS) based on 2,2,6,6-tetramethylpiperidine. The UV absorber reduces the rate of generation of free radicals, and the light stabilizer reduces the rate of oxidative degradation by free radicals.

TYPES OF COATINGS

Paints and coatings can be classified in several ways: by application area, as with architectural versus industrial coatings; by the nature of the binder delivery system, as with evaporative versus nonevaporative coatings; or by the thermochemical properties of the ultimate dry film, as with convertible versus nonconvertible. Arguably, the most basic classification of paints and coatings is according to functionality: sealers, primers, and topcoats. A sealer is used to inhibit capillary action in a porous substrate such as masonry or wood, and is clear or only lightly pigmented. It provides a uniform base for the primer and prevents the migration of extractives from the substrate into the primer and to topcoats. A primer is usually highly pigmented, providing a dense and relatively inflexible film. It assists in protecting the substrate, provides a physically and optically uniform base for the topcoats, and ensures the adhesion of the coating system to the substrate. The top or finish coats are less dense and more flexible than the primer coat, providing the final protective and aesthetic layer.

Architectural Coatings

Architectural coatings are the paints used to protect and decorate the exterior and interior of buildings. They are also called "trade sales paints" when sold through retail outlets. These coatings are most often applied to wood and drywall to control moisture absorption, swelling, and degradation while providing a durable, flexible, and decorative film. Interior and exterior paints are produced in both solvent- and waterborne formulations yielding a flat, semigloss, or gloss finish. Waterborne latex paints dominate trade sales markets because of their ease of handling, application and ease of cleanup, nonflammability, and low hydrocarbon solvent exposure. Within the collective architectural coatings are those formulated for more specific performance. Masonry coatings, for example, are used to prevent surface deterioration, to block the passage of moisture and

extractables, and to improve the appearance of concrete, brick, stone, and tile.

Industrial Coatings

Industrial coatings are designed primarily to protect metal surfaces. Exposed ferrous surfaces oxidize rapidly to a nonprotective oxide coating. Liquid coating systems for ferrous metals are therefore typically based on primers containing a linseed oil or alkyd binder and anticorrosion pigments such as red lead, lead chromate, zinc chromate, potassium zinc chromate, and zinc dust. Primerless, direct-to-metal, protective latex coatings are also used. Although nonferrous metals tend to form an oxide layer that protects against further deterioration, they may require a coating to protect the surface from deterioration other than oxidation or, with a clear coating, to preserve the appearance of the unoxidized metal. Coil coating refers to a continuous process of applying a coating to a coil of steel or aluminum strip or sheet. The coated metal is formed into many colored metallic products such as appliance and electronics housings, roofing and siding materials, window blinds, and furniture components. The common coil coatings are based on amine alkyds, epoxies, vinyl alkyds, solution vinyls, thermoset resins, solvent-type and water-reducible polyesters, and fluorocarbon resins. Many items, particularly appliances, which were once coil coated are now powder coated.

Marine coatings are used on marine vessels and equipment. They are formulated to retard corrosion and fouling and generally to protect against the harshness of the marine environment. A ship coating system typically consists of a preconstruction primer with corrosion-inhibiting properties, a multipurpose repair primer, a ship bottom coating, antifouling coatings, topside coatings, and deck coatings. The environmental conditions in which the vessel or equipment is required to operate determine the composition and use of marine coatings.

Automotive finishes provide a high level of protection to the vehicle's substrate and an aesthetically appealing appearance, so that the vehicle retains its original look for as long as possible. Because of the consumer expectation of high-finish-coat quality, the primer coat must provide excellent adhesion and corrosion resistance as well as a uniform, smooth surface for the topcoats. The finish coats must be compatible with the prime coat and form a final hard, protective, blemish-free film that can be polished and repaired.

Convertible and Nonconvertible Coatings

Coatings are also classified as convertible or nonconvertible, according to the nature of the dried or cured film. A convertible coating reacts chemically during film formation, converting the polymeric binder into a three-dimensional cross-linked network. Cross-linking may be effected through an oxidative mechanism, as with oil and alkyd paints; catalysts, as with UF coatings; amine curing agents, as with epoxy systems; or UV radiation. The film is permanently altered and cannot be reliquified by heat or contact with most solvents.

Nonconvertible coatings form thermoplastic films, usually through the evaporation of organic solvent or water. Solvent coatings, in simplest terms, are made by dissolving a polymer of suitably high molecular weight at sufficiently low concentration to obtain the appropriate coating viscosity. As the solvent evaporates, the resin concentration increases, forming first a tacky film and then the final polymer film after the solvent is completely released.

Aqueous coatings are typically a latex emulsion consisting of colloidal polymer particles, usually smaller than 0.5 μm , that are

stabilized with an emulsifier to prevent flocculation and coalescence. After a latex paint is applied, water begins to evaporate and the polymer particles become increasingly concentrated. The particles eventually touch and pack together, leaving voids filled with water, which must eventually be lost to evaporation or porous absorption by the substrate. Eventually, the particles completely coalesce and fuse into a continuous film. Coalescing agents are used as temporary plasticizers, so that as the water evaporates, they have an increasing softening effect on the polymer particles, helping them coalesce more easily.

Evaporative and Nonevaporative Coatings

Yet another way to consider coatings is according to whether or not film formation depends on the loss of volatiles, either water or solvent.

Evaporative Coatings

Evaporative coatings include the conventional solvent-borne and aqueous emulsion types described in a previous section. For solvent coatings, high-solids systems, containing less than 30% volatile organic solvents, are generally preferred for environmental reasons. The viscosity of these systems is maintained sufficiently low for acceptable application properties by using oligomeric binders with carefully controlled molecular weight distributions and reactive diluents such as unsaturated monomers. Coatings with water-soluble binders are made with convertible resins modified with carboxylic, hydroxyl, or amino groups. These are essentially solvent coatings with water as the solvent. Polymeric film formation occurs in a sequence similar to that described for solvent coatings, with the final film oxidatively cross-linked.

An important factor in the production of an evaporative coating is the dispersion of the primary and extender pigments in the vehicle. To provide a uniform film with the desired surface characteristics, agglomerates must be broken down by mechanical shear into finely divided particles coated with the vehicle. Deagglomeration, particle-size reduction (if necessary), and dispersion are accomplished in a variety of equipment, from the conventional roller mills, ball mills, and pebble mills to high-shear media mills and dispersers. High-shear media mills are the most common type used in the production of paint and coatings. These mills can process high volumes of a wide range of coatings formulations, from very fluid compositions to high-viscosity materials, at relatively low operating cost. They consist of a hollow cylindrical shell with a rotating vertical or horizontal shaft and discs or pins located intermittently along the shaft length. These drive the grinding media through the coating formulation at very high velocity. The grinding media can be specially sized sand or, more commonly, small steel or ceramic balls. Media mills can be incorporated into either batch or continuous production processes.

The high-speed disperser is used in batch operations because of its relative ease of operation and cleanup. The viscosity of the formulations appropriate for this type of equipment must be in a well-defined range. If the viscosity is too low, no shearing action will occur, and if the viscosity is too high, the movement of the particles will not be rapid enough to break the agglomerates.

Evaporative coatings are typically produced in two steps: the "pigment grind" and "letdown." For example, with a waterborne coating, the pigments and extender pigments are first thoroughly dispersed into a portion of the water and glycol to which surfactant, dispersant, and defoamer have been added. This pigment concentrate is then diluted or "let down" with the balance of water plus binder, coalescent, thickener, and other additives.

Nonevaporative Coatings

Two component catalyzed systems are used as nonevaporative liquid coatings. One component contains a reactive polymer such as an epoxy, and the other contains the cross-linking agent. After the two parts are mixed, the coating has a limited pot life during which it must be applied before reaction and hardening occur. Thicker films can be obtained from this type of coating than are practical or possible from evaporative coatings.

Radiation cure coatings are typically solvent-free, high-solids systems based on acrylated epoxy or urethane oligomers with multifunctional acrylate monomers as diluent. These coatings cross-link rapidly at ambient temperature on exposure to UV or electron beam radiation. This makes them particularly suitable for heat-sensitive substrates such as paper, wood, and certain plastics. Because radiation intensity varies significantly with distance between the radiation source and the coated substrate, this technology is used almost exclusively on flat or rotatable cylindrical objects. Infrared and microwave cured coatings are sometimes also considered radiation cured, but in these systems the radiation is simply converted to heat, which initiates thermal curing.

Electrodeposition coatings for metal use water for its electrolytic properties rather than for its volatility. Binder particles, usually thermoset resin, are dispersed in an aqueous vehicle. The metal part can serve as either anode or cathode. In anodic systems, current causes the negatively charged paint particles to deposit on the anode through precipitation by the hydrogen ions generated there by electrolysis of the water. In cathodic systems, the positively charged paint particles deposit on the cathode through precipitation by generated hydroxide ions. Film thickness is essentially self-limiting because as film thickness increases, electrical resistance increases and deposition rate decreases until the film thickness at which deposition stops is reached. The coated article is removed from the electrodeposition bath, rinsed, and baked to cure. Because the entire surface of the metal object acts as an electrode, electrodeposition coatings are used to provide complete, void-free coverage. This is of particular value in the application of anticorrosion coatings.

Powder coatings use air as the medium through which resin is applied. Powder coatings are most often applied to bare metal as an electrostatic spray. The metal is grounded and the powder is given a negative electrostatic charge by the spray gun. The powder particles coat the metal surface through electrostatic attraction. Coverage tends to be uniform but self-limiting because the coating of powder acts as an insulator. The powder-covered article is baked, allowing the powder particles to fuse to a continuous film, flow, level, and cross-link. Heat-tolerant plastics and previously coated metal can be powder coated after preparation with a conductive primer. Powder coatings are widely used as industrial finishes on appliances, machinery, and outdoor fixtures and furniture because they provide a hard durable coating with essentially no VOC emissions and nearly 100% powder utilization—any overspray is easily collected and reused.

The coating powders are actually more like formulated plastics than like paint resins. They are prepared by premixing all ingredients (resin, pigments, extenders, reinforcements, and additives), melt extruding, and then pulverizing. Powder coatings are generally based on epoxy or polyester binders, although acrylic binders are used for particular applications such as for superior detergent resistance on washing machines. Thermoplastic powders, based on vinyl chloride copolymers, polyamides, fluoropolymers, and thermoplastic polyesters, are less commonly used because they are difficult to pulverize to fine particle sizes, resulting in relatively thick films, and because they provide relatively poor flow and leveling.

Thermoplastic powders are used in fluidized bed coating, although the resultant films are still relatively thick. The article to be coated is heated above the T_g of the binder resin and then suspended in an air-fluidized bed of coating powder. Powder particles fuse onto the hot object until the powder layer becomes thick enough to act as a thermal insulator and prevent additional fusing. The operation is completed in a separate oven, since the surface may contain incompletely fused particles. Electrostatic fluidized beds are also used, with charged powder and grounded substrates, which may or may not be preheated.

Flame spray technology is also used to apply thermoplastic powder coatings. A flame spray gun instantaneously melts the powder as it is sprayed so that the molten plastic flows and fuses onto the article. This process can be used on nonconductive, heat-tolerant surfaces such as concrete, wood, and certain plastics in addition to metals. It has the advantage of portability over the other powder-coating techniques, which require a large-scale, carefully controlled industrial setting. Flame spray apparatus can be used in the field to coat objects and to repair previously applied thermoplastic flame spray coatings.

TEST METHODS

The test methods employed in the evaluation of paints and coatings fall into two basic categories:

1. Those tests used to evaluate the properties and characteristics of a coatings formulation for a particular application
2. A selected subset of these tests used for the quality control of production material

The most widely used quality control tests for paints and coatings are described in the sections that follow.

Solids Content

The “solids” of a paint include all nonvolatile components that remain in the dry paint film. Measuring solids is important to ensuring control of the manufacturing process. Paints that deviate from the specified solids content may have variations in color and film durability. The solids content is also important in calculating the amount of coverage a paint will provide.

Specific Gravity

Specific gravity is an important, easy-to-measure property that indicates the weight of the paint for a given volume. Specific gravity is used as an in-process quality control test and as an end-product test to determine if all the major components were added in the correct amounts. It can be measured simply by filling a tared container of known volume and then weighing. For a higher level of precision, pycnometers are used.

Fineness of Grind

During the dispersion process, it is important to be able to measure the degree of breakdown of agglomerates and aggregate particles. If the grind is not fine enough, poor color uniformity, gloss, or hiding power can result. A convenient tool for measuring the “fineness of grind” is the Hegman gauge. This is a steel plate having a channel of declining depth from 0 to about 100 μm . Samples are drawn over the gauge with a straightedge. The depth of the channel at which particles are evident is taken as the Hegman reading for particle size. Table 4 lists Hegman fineness and corresponding channel depth. Hegman fineness of grind is commonly used as a specification test for mineral extenders to ensure that they do not contain any particles that are too large for the intended coating film.

Table 4. Hegman fineness and size (as channel depth)

Hegman Fineness	Channel Depth, μm
0	101.6
½	95.3
1	88.9
1½	82.6
2	76.2
2½	69.9
3	63.5
3½	57.2
4	50.8
4½	44.5
5	38.1
5½	31.8
6	25.4
6½	19.1
7	12.7
7½	6.4
8	0

Viscosity

Viscosity measurements are taken as in-process tests and end-product tests. Simple viscosity tests such as the Ford cup and Zahn cup tests measure the time required for a given volume of sample to pass through a standard size orifice. The Brookfield viscometer measures viscosity from shear resistance on a standard spindle rotating at a constant speed. A Stormer viscometer measures the time required for a standard paddle to revolve 100 revolutions from a constant force provided by a weight and pulley. The Gardner-Holdt bubble viscometer is used for varnishes. It quickly indicates varnish viscosity by measuring the time required for a bubble to rise to the top of a standard tube after being inverted under standard conditions. The problem with most viscometers is that they measure viscosity at relatively low shear. They can be used as good production control tests, but they do not necessarily relate well to the paint's rheology when applied under high-shear brush, roller, or spray application.

Wet Hiding Power

To measure the ability of the wet coating to produce an opaque film, it is uniformly brushed onto an impervious, black-and-white striped surface until complete hiding is achieved. The weight of the coating required to do this is determined and the hiding power in square feet is calculated. Wet hiding power is inversely proportional to coverage: the more paint needed, the less area that can be coated per gallon.

Dry Hiding Power

The dry hiding test uses the same striped panel and coating procedure previously described. Five brushouts are made, however, applying a different amount of paint each time. After each brushout, the panels are allowed to dry for 24 hours, and then the contrast ratio is measured. Contrast ratio is equal to the reflectance over the black area divided by the reflectance over the white area. The weight of the paint is plotted against the contrast ratio, and the amount of the paint required to give a contrast ratio of 98 is read from the resulting curve. The dry hiding power is calculated accordingly.

Specular Gloss

A 60° gloss reading on a standardized test panel is used to determine film smoothness and thus visual gloss. Increases in surface

roughness or imperfections promote diffuse reflection and lower gloss.

Color

The color of a finished coating can be qualitatively evaluated by visual comparison to an established standard. Most color comparisons, however, are made quantitatively by measuring test panels on color measurement instruments that calculate color coordinates and determine the color difference.

Table 5 lists the recognized American Society for Testing and Materials (ASTM) procedures used primarily for evaluating coatings formulations and determining coating characteristics.

TRENDS AND OPPORTUNITIES

Improved coating properties and lower emissions of volatile organics have been concurrent goals of the coatings industry for many years, with the latter often frustrating progress toward the former. Lowering VOCs is an ongoing process of replacing solvent-borne coatings with waterborne and solventless (organic solvent and water-free) alternatives. Because mineral extenders exert considerable influence on the rheological, optical, and performance properties of coatings, manipulation of particle size, shape, and surface properties remains a challenge and an opportunity. Low extender vehicle demand is preferred, for example, when formulating high solids and 100% solids coatings. This is an opportunity for the producers of naturally low demand extenders and a challenge to the producers of conventionally high-performance but high-demand extenders.

An appreciation of particle-packing phenomena is increasingly important as the coating formulator strives to optimize the extender loading for the required balance of application properties, optical properties, durability, and substrate protection. Emphasis is accordingly placed on manipulating the distribution of particle shapes and sizes of the minerals sold as extenders. The surface properties of extenders are likewise subject to further customization. Because most mineral extenders have hydrophilic surfaces, modification with additives such as silanes and titanates becomes more important to ensure compatibility with and reinforcement of the coating polymer film. This is reasonably straightforward for nonaqueous coatings, but less so for waterborne alternatives. The mineral surface must be sufficiently hydrophobic or even reactive for greater functionality in the binder film without being unduly difficult to disperse intimately in the aqueous vehicle.

Plastics

George Hawley

INTRODUCTION

Plastics can be defined as a mixture of polymers with additives. The polymer is a long twisted chain made up mainly of methylene groups, but it may also contain some amino and carboxyl groups. Side chains and substitute groups for hydrogen are also common. Industrial minerals and their derivatives are used as additives to overcome some of the deficiencies of the properties of plastics when compared to metals and cementitious materials. These additives may be roughly divided into a filler, which contributes some bulking and cost-reduction properties but is mainly used to improve some physical property, and an extender, which is used to augment the hiding power of a primary pigment and reduce cost. Favorable properties conferred by these additives are enhanced stiffness, strength, hardness, impact resistance, surface appearance, opacity, dimensional stability, thermal stability, service temperature, fire resistance, permeability to gases and liquids, chemical and solvent resistance, dielectric properties, thermal conductivity, electrical properties, resistance to ultraviolet (UV) and other radiation, and processability. These same improvements may be achieved through the use of specialty polymers or by chemical additives, but at much higher cost (and often the mineral confers a balance of several different property enhancements). At the same time, mineral additives may have an adverse effect on certain properties such as flexibility and impact resistance.

The leading mineral additive used in the plastics industry is dry or wet ground calcium carbonate (GCC) or dolomite, followed by talc, kaolin, mica, wollastonite, natural and synthetic silicas, aluminum hydroxide, and precipitated (synthetic) calcium carbonate (PCC).

Some of the more common polymers used in the plastics industry are

- Polyolefin—polymer composed of chains of carbon atoms with hydrogen or methyl side groups (e.g., polyethylene, polypropylene)
- PVC—polyvinyl chloride polymer
- PP—polypropylene
- PE—polyethylene (HDPE, high-density PE; LDPE, low-density PE; LLDPE, linear low-density PE)
- PA—polyamide (nylon)
- PS—polystyrene

- ABS—acrylonitrile-butadiene-styrene copolymers
- SMC—sheet molding compound
- BMC—bulk molding compound
- RRIM/PU—reinforced reaction-injection molded polyurethane

TYPES OF PLASTICS

Plastics are generally divided into two classes: thermoplastics and thermosetting. Thermoplastics are solid polymer pellets that can be melted and molded into specific shapes. They can also be recycled by remelting and remolding. Although there is some degradation with each melt cycle, up to 30% of a recycled thermoplastic can be used in a final product with no significant effect on properties, providing that stabilizing additives are used. Typical thermoplastics are PVC, PP, PE, ABS, and PA.

Thermosetting polymers are usually liquids at room temperature (because heat causes decomposition). They require the addition of catalysts to convert the polymer into a solid by cross-linking reactive groups on the chain. Once “cured,” the polymer is infusible. Thermosetting polymers are not usually recycled, unless pulverized and used as a filler. Typical thermosets include epoxy, unsaturated polyester, and polyurethane.

Plastics are further divided into amorphous, crystalline, and semicrystalline types. Amorphous polymers tend to be low in cost and to have more flexibility and good impact resistance, but they also exhibit low strength and stiffness characteristics. Typical amorphous polymers are LDPE (as used in agricultural and packaging films), PS, and ABS. In contrast, crystalline polymers tend to have higher strength and stiffness but lower impact properties. Crystalline polymers include PP, HDPE, and LLDPE.

MINERAL FILLERS IN PLASTICS

In general, when minerals are incorporated in plastics, they reduce shrinkage on demolding and speed up the molding cycle. Negative effects are the lowering of strength, impact resistance, and flexibility. Filler content usually increases plastic density to a specific gravity (SG) of about 1.5 compared to that of unfilled polymer, which ranges from 0.9 to 1.1. Although this is generally deleterious, the improved plastic properties may make it possible to substitute for steel at SG 7.0, leading to substantial weight savings. This is a major factor that is spurring the automobile industry, for example, to switch to plastics.

Table 1. World consumption of major fillers in plastics (2002)

Filler	kt	%
GCC	7,250	66
Talc	660	6
Kaolin	660	6

* Includes silicas (natural and synthetic) and alumina hydrate.

Table 3. Consumption of ground calcium carbonate in plastics, by country

Country	Mt	%
Asia/Oceania	3.2	43
China	2	27
Japan	0.5	7
South Korea	0.3	4
European Economic Community (EEC)	1.7	23
United States	1.5	20
South and Central America	0.4	6
Middle East and Africa	0.6	8
Total	7.4	100

Mineral fillers act as true reinforcements only in crystalline polymers. One of their beneficial functions is to catalyze crystallization. In addition to their generic effects, mentioned previously, they increase strength, stiffness, and heat resistance. These plastics tend to warp on cooling because of the orientation of the crystallites in the flow direction, which results in a substantial differential in thermal contraction in the flow and cross-flow directions. This problem is worsened by fibrous fillers but is improved by using flake minerals such as mica, talc, kaolin, and graphite.

PROCESSING OF MINERAL-FILLED PLASTICS

Mineral-filled plastics are processed by the same machines as the unfilled versions. The main processes used are extrusion, blow molding, and injection molding.

In extrusion, the largest volume process, the plastic is melted, forced through a die to give the correct profile, and then cooled to set it. Typical products are pipes, tubing, siding, door and window

profiles, and window blinds, and typical filled polymers used are PVC, LDPE, PP, HDPE, and ABS. In a variation of this process, a pipe is extruded and then blown by internal air pressure to a bubble of the correct thickness, making film. Films of LDPE, LLDPE, PP, and HDPE are not generally filled, except in specialty applications such as diapers (see section on GCC in Microporous Films in this chapter). These films represent a huge market.

In blow molding, a variation of extrusion, a pipe section is extruded into a mold where internal gas pressure forces it to take its shape. All plastic bottles and drums are made by this process, as well as toys, air-conditioning ducts, and seat backs in cars. Typical filled polymers used are PVC, PP, LDPE, HDPE, and ABS.

In injection molding, the molten plastic is injected into a closed mold that is then cooled to set the plastic. This is the most common way to make three-dimensional plastic objects ranging from tiny computer contacts to 1,500-lb. truck cabs. Although all thermoplastic types are used, the most common are PVC, PP, PE, PA, and ABS.

One variation of this process is thermoset injection of filled sheet and bulk molding compounds where the mold is heated to cure the polymer. This process is used with unsaturated polyesters to make BMC plumbing fixtures (such as laundry sinks and shower pans) and SMC automobile parts (such as hoods and trunk lids). BMC and SMC contain high levels of GCC.

Another variation is RRIM/PU, in which mica- or wollastonite-filled polyurethane or polyurea liquid polymers are forced into molds. Very large parts such as truck cabs can be made with this low-pressure process. The largest end use is for front and rear fascias and wraparound fender assemblies on most cars.

Supply and Demand

The size of the market for minerals used in plastics is small relative to the large-scale commodity markets often served by the same suppliers. In fact, the fines from the production of mineral products used for the metallurgical, ceramics, and glass industries are often the starting point for production of mineral fillers. Overall, the supply of mineral fillers exceeds demand. To counter the relatively small tonnage of minerals required, however, the plastics market is important in that it requires more specialized products that command higher prices and generate higher profits. It is estimated that the total tonnage of mineral products used in the plastics industry worldwide exceeds 10 Mt (see Tables 1–3).

Prices

Prices range from \$0.02/lb to \$0.05/lb for coarse commodity-like powders and up to \$4.00/lb for sophisticated, high-tech products such as nanoclays (see Table 4).

Classification

Natural Fillers

Carbonates are by far the largest volume of minerals used. In this class, calcium carbonate with some dolomite predominates because its higher hardness lends increased durability to floor tiles. Silicates are the next largest class, mainly as talc, followed by kaolin. Wollastonite and mica, although relatively low-volume minerals, command high prices because of their unique reinforcing abilities. Magnesium minerals such as brucite, huntite, and hydromagnesite are used in small amounts as a flame retardant. Silica is used for its high hardness, chemical resistance, and thermal conductivity. Graphite consumption is currently small but has great potential for increased use in electrically conductive plastics—in particular, in fuel cell plates and antistatic plastics.

Synthetic Fillers

Alumina hydrate, the largest of the synthetic mineral products used in plastics, is used as a flame retardant in carpet backing and plumbing fixtures. Synthetic silicas are mainly used as thickening agents in liquid polymers, as reinforcements in silicons, and as antisticking agents in films. Precipitated calcium carbonate is used in plastics, but to a much lesser extent than GCC. Some magnesium hydroxide is also used but in small volumes, although this should increase because competitive fire retardants are being banned.

General Considerations

The demand for and value of industrial minerals increases with enhancements in the following characteristics:

- Purity—Heavy metals, toxins, and environmentally undesirable impurities are absent.
- Color—Generally, the highest whiteness or blackness is preferred.
- Fineness—The finer, the better. The trend is to submicrometer and increasingly, to particles that have their larger dimension in the nanometer rather than the micrometer region (with a narrow range).
- Surface modification—This improves particle dispersion and optimizes property enhancement by improved bonding.

INDUSTRY STRUCTURE

Infrastructure

Although it is obvious that a mine may not be sited near the end user, secondary processing can and should be located near the point of consumption. The use of minerals in plastics is highly technical, requiring a highly trained staff, and R&D is often conducted in concert with university and government laboratories. Fine grinding is energy intensive, necessitating that a significant power source be nearby. Technological requirements are for fine comminution, control of agglomeration, surface chemistry, and awareness of current status and future directions of the plastics industry.

Barriers to Entry

Supplying the plastics industry is a marketing-driven business. Technological expertise is mandatory, as is a deep purse, because penetration into markets such as automotive, aerospace, and medical/dental supplies may take 4 years or more. User confidence is hard won and ISO (International Organization for Standardization) certification is a must. The producers tend to be a small number of global suppliers of a suite of minerals that are supplied to all the markets, including plastics. These producers have sophisticated special-purpose laboratories that are equipped for plastics R&D work; these laboratories also enable producers to furnish the specialized technical services required by their customers.

Economic Factors

For the lower-value industrial minerals, the freight costs may be as high as the mineral value. For this reason, location near the markets or near low-cost transportation avenues such as waterways may be vital. Markets are now global and it may be less costly, for example, to supply Europe by sea than to truck product to a North American user. Major suppliers seek out mines and locate processing facilities as near to their customers as possible.

Specifications

The end user sets the specifications—even in the same application, different end users may specify products that vary widely in charac-

Table 4. Pricing of major minerals used in plastics

Mineral	Specification	\$/t
Calcium carbonate		
	GCC	
	45 μm	50–100
Fine PCC	5–7 μm	110–160
	0.5–2.0 μm	140–290
	0.4–1.0 μm	250–270
Ultrafine treated PCC	0.02–0.36 μm	375–750
Talc		
	20–25 μm	185–195
Kaolin	10–20 μm	200–205
Wollastonite	Hydrous filler	80–185
	Calcined	320–375
	200 mesh	205
	325 mesh	248
Mica	400 mesh	275
	High aspect ratio	345–1,000
Mica	Dry ground	210–400
	Micronized	535–930
	Wet ground	535–1,300

ter. Particle sizes range from 140 μm down to submicrometer and even nanometer sizes.

PRODUCTION TECHNIQUES

Raw and Intermediate Materials

Originally, filling plastics was regarded as a way to dispose of unwanted fines—for instance, fines from marble, soapstone, or calcium carbonate aggregate operations. Subsequently, user requirements became more restrictive and, because the prices commanded were orders of magnitude higher than those of the original end use, it became normal practice to produce fillers directly from ore. Ores are sought that are high in purity; preferably little or no beneficiation should be required. This is possible with carbonates, talc, silica, and some clays. With other silicates such as mica and wollastonite, however, beneficiation is normally required.

Mining and Processing

In general, mining methods used are conventional; carbonates and silicates require drilling and blasting, and clays are commonly mined using scrapers or loaders. Small amounts of large sheet mica and lump graphite are mined by hand for high purity, to produce larger-size flakes or lumps, or to preserve the character of the deposit.

Initial size reduction is generally by jaw crusher followed by hammer mills. Beneficiation may be by flotation, but residual reagents may interfere with performance in plastics. Dry processes such as gravity and magnetic and electrostatic separation are preferred and are also less harmful to the environment. Low-value products may be made by ball milling, but this process generally reduces the quality of minerals such as mica, wollastonite, and graphite. Hammer and cage mills are used to make products down to 20 μm . Air-swept mills reduce these products down to 2–10 μm . Fluid-energy milling is the standard method for producing finer particles, but it is costly in capital expense and operations. Stirred-media

Table 5. Surface modification and treatment

Chemical Type	Fillers	Wt % on Filler
Stearic acid and stearates	Calcium and magnesium carbonates	1–3
Silanes	Silicates (mica, wollastonite, kaolin, and talc); natural and synthetic silicas; oxides (titanium dioxide and iron oxides)	0.25–2.0
Titanates, zirconates, zirco-aluminates	Silicates, silicas, and oxides, plus carbonates	0.5–3.0
Carboxylated polymers	Mica, wollastonite, talc, kaolin	5–25
Chlorinated hydrocarbons	Mica, wollastonite	1–5

milling and vibro-energy milling are less expensive and are being used increasingly to make the finest particle sizes.

The filler surface is commonly treated. This may involve surface modification whereby the filler is reacted with a chemical that in turn reacts with the polymer to form a large molecule, ensuring that the polymer bonds to the filler (see Table 5). Or surface treatment that encourages wetting of the filler by polymer may be applied to the filler, improving dispersion and reducing viscosity. Surface treatment does not form any chemical bonds and is reversible.

Other treatments include pelletization or granulation to reduce dustiness and air entrainment and to facilitate feeding into plastics-compounding equipment.

FINISHED PRODUCTS

Specifications

Specifications always include particle-size analysis that is given as a curve or as quoting a average and top size. Surface area is commonly quoted because it is a measure of particle size. Moisture content is a required measurement, because moisture is deleterious to most plastics. Brightness is often quoted for white fillers. Other common measurements quoted are refractive index, pH, specific gravity, bulk density (loose and compacted), oil absorption, and water-soluble salts. Chemical composition is sometimes quoted but is of no real interest to the plastics end user.

Uses and Applications

As previously discussed, industrial minerals and their derivatives are used as low-cost functional additives in plastics to overcome some of the deficiencies of the properties of plastics when compared to metals and cementitious materials. The more common minerals are outlined in the following sections.

Ground Calcium Carbonate

GCC in PVC

GCC, by far the most important filler mineral used in the plastics industry, is used in large volumes in PVC. The main functions are as

- A low-cost opacifier, substituting for titanium dioxide
- A stabilizer against thermal degradation during processing
- An agent to increase service temperature to protect against weathering
- An agent to increase stiffness and surface hardness
- An agent to reduce shrinkage out of the mold
- An agent to increase chemical resistance
- An agent to improve impact properties
- A processing aid to increase throughput

GCC is used extensively in PVC sewer, pressure, and potable water pipes; fittings; floor tiles and other flooring; outdoor furniture; window and door extrusions; automobile plastics; leathercloth; wallpaper; and blinds. GCC is used at levels of 20%–30% by weight of products ranging from 1 to 5 μm . The level is much higher in flooring (up to 70%) using coarser particles (325 mesh and larger).

GCC in PP

The second largest use of GCC is in polypropylene—approximately 500,000 t of filled polymer in each of the EEC countries and in the United States. The filler level is 20%–60% of 1–3- μm GCC. End uses include

- Automotive (interior and exterior trim, under-the-hood parts)—53%
- Appliance parts—24%
- Garden furniture—8%

GCC in Microporous Films

Although polyolefin film is a huge market, it has not used much filler in the past except some GCC, PCC, talc, and diatomaceous earth at levels of 2%–5% as antiblocking agents. A new market has developed and grown rapidly—the production of microporous films, which hold liquid water but allow water vapor to pass through. These have become an industry standard in diapers, with a 65% market share in the United States, 50% in the EEC, and 40% in Asia. GCC content is 43%–70% by weight, with particles 1–2 μm in size. Another growing market is film underlay for walls and roofing. Current consumption is about 100,000 t and growing.

Other Minerals

Talc is mainly used in PP and HDPE where its hydrophobic nature ensures good compatibility without surface treatment. Talc-filled plastics tend to scratch easily and are being supplanted by GCC in wear-prone applications. End uses are automobiles, appliances, housewares, and business machines.

Kaolin is largely limited to use in electrical wire and cable, and calcined kaolin is the preferred type. Calcination converts the kaolinite to mulite, spinel, and cristobalite. Because it is anhydrous, it has excellent electrical properties. Surface treatments are used to improve adhesion and thus mechanical and electrical properties. Mica and wollastonite are used—mainly in polyolefins, polyamides, and polyurethanes—to increase stiffness, strength, and surface hardness, as well as to reduce shrinkage and warping. The main end uses are in the automotive industry (i.e., interior/exterior body parts, under-the-hood parts, glove boxes, and fender liners), and in dishwashers, washers, tubs, and pumps. Silane treatments are common for enhancing mechanical properties.

Competitive Alternatives

Ironically, industrial minerals tend not to reduce the cost of a plastic article because their high specific gravity (2.5–3.0) versus that of polymers (0.9–1.1) means that it takes 2.5 to 3 times the weight of filler to replace the same volume of polymer. Thus, to compete with PP at SG 0.9 and a cost of \$0.45/lb, the competitive price of a calcium carbonate filler would have to be about \$0.15/lb. This also ignores the cost of compounding the filler into the polymer, which may be \$0.15/lb or more.

Because the only true cheap filler is air or another gas, plastics may be foamed, but this reduces the mechanical properties greatly and some additional filler is required. With improved vehicle fuel efficiency (Corporate Average Fuel Economy [CAFE])

standards for U.S. passenger cars and light trucks invariably mandating weight reductions, the use of dense fillers is a problem for the automotive industry. This has encouraged the use of wood fillers in nonstructural applications. Synthetic wood for decks and benches are fast-growing markets for wood-filled HDPE. Glass fibers are by far the largest reinforcing filler used in plastics. But the growth of carbon fibers has increased with its reduction in cost, and with an SG of 2.0 (versus 2.65 for glass) and much higher reinforcing properties, carbon fibers will find more applications in automobile end uses.

MARKETING AND DISTRIBUTION

Use-Specific Marketing and Transportation

Because it is common for grades of minerals to be produced that are specific to a certain segment of the plastics industry—such as automotive, PVC profiles, and packaging—use-specific marketing is the dominant force in the industry. These are almost commodities, but there is enough variation among individual plastics end users that special subgrades must be tailor-made for a user's specs or even for that user's particular plant. The result is that the filler producer must make dozens of grades from each ore body. Selling to these markets is highly technical, and sales engineers with plastics experience are the norm and are supported by major investments in technical service and research laboratories.

The filler manufacturer normally has its own sales force. Small orders are often handed off to distributors who stock small amounts and service small accounts for a commission fee of 10% or so.

The regular packaging in the filler industry is 25-kg or 50-lb multiwall paper bags on pallets, but the industry is moving toward packaging in cardboard Gaylord boxes or woven plastic semibulk bags that contain 500–2,000 lb of product. The decision is one of economics. Paper bags are cheaper and need no special handling, but they are labor intensive. Bulk bags need special handling equipment, but the product is not prohibitively expensive. Very large compounders buy in bulk, and they find putting in bulk tanks and distribution systems to be cost-effective. Bulk handling, however, creates special problems for the filler supplier.

Just-in-time delivery is the norm and, in North America, this is best supplied by trucking. Vans carrying 40,000-lb loads are preferred for protection against the weather. Over a long haul, some cost advantages may be realized by piggyback road/rail transportation. Boxcars may carry up to three times the amount of material, but the load must be bulk-headed to prevent damage because of the poor quality of the track in some areas. Overseas shipments are handled by 20- or 40-ft containers, or by bulk bags carried in bulk carriers on top of the regular large-volume bulk commodity.

GOVERNMENTAL, ENVIRONMENTAL, AND HEALTH CONSIDERATIONS

Since the 1970s, the health effects of the unintelligent use of industrial minerals have become apparent, with the correlation of, for example, exposure to asbestos fibers with cancer. Regulations that control the production and utilization of fibers in the workplace are now in place. This affects not only asbestos itself but also any mineral that contains asbestiform fibers. Minerals where such fibers have been found or may be present include talc, vermiculite, and wollastonite.

The World Health Organization has classified fine crystalline silica as a carcinogen, triggering regulation that controls its use in the workplace. Silica is a very common impurity in most industrial minerals.

Lead has also been classified as a serious health hazard, as have other heavy metals such as chromium and toxic elements such as arsenic.

Minerals producers must determine that their products do not contain any of these compounds in regulated amounts, and also ensure that they are not releasing such agents into the atmosphere or into groundwaters.

TRENDS AND OPPORTUNITIES

The trend is toward substitution of plastics for conventional materials, not only because of cost but because the final products can be made very rapidly and much more cheaply, with less energy and more design flexibility. Wood products are becoming scarcer and more expensive. Cement-based products are very energy intensive and much more polluting than plastics; about 5% of all Canadian carbon emissions, for example, come from cement production. Metals are heavy, energy intensive, limited in design potential, have to be protected or decorated, and are more expensive on a volume basis than plastics. Plastics growth, which is virtually recession proof, is expected to continue at an average rate of 2%–3% per year.

Trends in filler production are toward finer particles down to submicrometer size and below. Opportunities exist in the production of nanometer-sized particles, which generally are much more effective as reinforcements for plastics. World production of nanocomposites was estimated in 2004 at only 104,000 t but has high growth potential. Modified montmorillonite clay, vermiculite, and graphite confer the same reinforcement characteristics at 2%–10% by weight that normally require 30%–40% of glass fibers, mica, or wollastonite. This increases product weight only slightly, a big advantage for the automotive and aerospace industries as well as the personal electronics industry. Other benefits include enhanced fire resistance without the toxicity of the conventional bromine-, chlorine-, and antimony-based additives—which are being classified as carcinogenic—plus reduced permeability to gases, especially oxygen, which is an important consideration for film packaging of meat.

Rubber

Peter W. Harben and Edward M. Dickson

INTRODUCTION

Elastomers are amorphous polymers that when mixed with various ingredients form a compound that can be “vulcanized” to produce rubber. They are elastic in that they can be stretched to several times their original length and can return or “bounce” back into their original shape without permanent deformation. In addition to being elastic and rubbery, these materials also dissipate energy because of their viscoelastic nature. They are further characterized by a great toughness under static or dynamic stress, an abrasion resistance that is higher than that of steel, an impermeability to air and water, and often a high resistance to swelling in solvents and attack by chemicals. Polymers that are elastomers include polyisoprene or natural rubber (NR) plus a host of synthetic elastomers, including synthetic isoprene rubber (IR), styrene-butadiene rubber (SBR), ethylene-propylene rubber (EPR), ethylene-propylenediene monomer rubber (EPDM), and nitrile rubber (NBR) (see Table 1).

Natural Rubber

Natural rubber exists as a colloidal suspension in milky white latex. This latex is the protective fluid made up of small particles of rubber dispersed in an aqueous medium and contained in tissue beneath the bark of rubber-producing plants such as the tree *Hevea brasiliensis* of the spurge family and other species in the same genus. These species constituted the sources of the original South American Para rubber, a commercial term that was applied to the rubber produced in the plantations of the tropics. Latex is collected as it exudes from a diagonal cut angled downward through the bark of the plantation trees that yield, on average, 450 kg/ha (400 lb/acre) of dry crude rubber per year with about 250 trees planted per hectare (100/acre). The gathered latex is strained, diluted with water, and treated with acid to cause the suspended rubber particles within the latex to clump together. After being pressed between rollers to consolidate the rubber into 0.6-cm slabs or thin crepe sheets, the rubber is air- or smoke-dried for shipment.

The resulting pure crude rubber is a white or colorless hydrocarbon with the simplest unit being isoprene (C_5H_8). The physical characteristics change as the temperatures change: rubber is a hard, transparent solid at -195°C (the temperature of liquid air); brittle and opaque from 0° to 10°C ; soft, resilient, and translucent above 20°C ; plastic and sticky when mechanically kneaded or heated above 50°C ; and decomposes above 200°C . Crude rubber is

insoluble in water, alkali, and weak acid, but soluble in benzene, gasoline, chlorinated hydrocarbons, and carbon disulfide. It is oxidized readily by chemical oxidizing agents and slowly by atmospheric oxygen. Crude rubber such as gutta-percha and balata from other plant sources is generally contaminated by an admixture of resins that must be removed before commercial use.

Synthetic Rubber

Synthetic rubber, defined as any artificially produced substance that resembles natural rubber in essential chemical and physical properties, is produced by the condensation or polymerization of certain unsaturated hydrocarbons. The basic units of synthetic rubber are monomers, which are compounds of relatively low molecular weight that form huge molecules called polymers.

Table 1 lists the main commercial synthetic rubbers. Neoprene, which was developed in 1931 and became one of the first successful synthetic rubbers, is the polymer of the monomer chloroprene [$\text{CH}_2\text{:C}(\text{Cl})\text{CH:CH}_2$] formed from acetylene and hydrochloric acid. Because neoprene resists heat and various chemicals such as oils and gasoline, it is used in hoses for gasoline and as an insulating material for cables and in machinery. In 1935, the buna-type rubber group was developed through the polymerization of two monomers including butadiene. (The name *buna* was derived from the initial letters of butadiene, used as one of the co-monomers, and natrium [sodium] used as a catalyst). One of the most popular buna rubbers, Buna-N, is based on acrylonitrile [$\text{CH}_2\text{:CH}(\text{CN})$] as the second co-monomer. Buna-N is resistant to the action of oils or abrasion. In 1940, butyl rubber was prepared by copolymerizing isobutylene with butadiene or isoprene. Although not as resilient as natural rubber and other synthetics, butyl rubber resists oxidation and corrosion and has low permeability to gas. Specialty synthetic rubbers include Koroseal, a polymer of vinyl chloride ($\text{CH}_2\text{:CHCl}$), which is heat-, electricity-, and corrosion-resistant and unaffected by exposure to light or long storage. Another is Thiokol, produced by copolymerization of ethylene dichloride (CHCl:CHCl), and sodium tetrasulfide (Na_2S_4), which when compounded and vulcanized like natural rubber is resistant to the action of oils and to organic solvents used for lacquers. Thiokol is useful for electrical insulation.

Other types include synthetic foam rubber, used mainly for upholstery, mattresses, and pillows, and cellular-crepe rubber, used by the shoe industry.

Table 1. Selected types and properties of rubber

Chemical Name	Common Name	Abbreviation	Properties
Isoprene, natural	Natural rubber	NR	Offer a good balance of properties with resilience and flexibility at lower temperatures. NR superior to most synthetics, but less resistant to chemical attack than some synthetics.
Isoprene, synthetic	Polyisoprene	IR	
Styrene-butadiene copolymer	SBR	SBR	Similar to NR
Terpolymer of ethylene, propylene, (with a small amount of diene)	EPDM	EPDM	Outstanding resistance to aging, weathering, and chemical attack. Low-temperature stability. Resistant to steam and water. Good resistance to glycol-ether hydraulic fluids, but not suitable for contact with petroleum liquids.
Isobutene isoprene polymer	Butyl	IIR	Very low gas and moisture permeability with excellent resistance to heat, aging, weathering, and ozone and chemical attack. Good electrical insulation properties. Not suitable for use with petroleum oils and fluids.
Chloroprene	Neoprene	CR	More resistant than NR to sunlight, ozone, and oxidation. Good resistance to heat, and softens less than NR under severe exposure. Not suitable for use with gasoline. Can be compounded to add flame-retardant properties.
Acrylonitrile-butadiene copolymer	Nitrile	NBR	Resistant to water, oil, fuel, and other petroleum products. Superior to most elastomers in compression set, cold flow, and abrasion resistance. Poor resistance to ozone, sunlight, or weather.
Chlorosulfonated polyethylene	Hypalon	CSM	Resistant to water, ozone, abrasion, flex cracking, acids, and weather. Good flame-resistant properties.
Polysiloxanes	Silicone rubber	"Q" Group	Resistant to temperature extremes (up to 2,000°C). Poor tensile strength, tear, abrasion, and steam resistance. Very good resistance to sunlight, ozone, and gases. Good electrical insulation and water repellent properties.
Polyesters	Polyurethane	AU	Abrasion resistant at moderate temperatures. Very high tensile strength, tear strength, and load-bearing capabilities. Resistant to oils, certain solvents, greases, ozone, sunlight, and weather. Poor resistance to acids and alkalis.
Fluorinated hydrocarbon	Viton	FPM	Resistant to most chemicals and commercial fluids. Retains strength at elevated temperatures and withstands embrittlement during long-term heat exposure.

PRODUCTION PROCESSES

Compounding

Raw rubber undergoes a mechanical grinding process called mastication that renders it soft, plastic, and sticky (i.e., it is plasticized). Commercial applications for uncured rubber, however, are limited to certain specialized cements; various adhesive, insulating, and friction tapes; and crepe rubber used in insulating blankets and footwear. Therefore, most rubber undergoes a process of curing or vulcanization, which imparts a permanent change and renders the rubber heat stable. Chemicals known as "curatives," which include vulcanizing agents, accelerators, and activators, facilitate this curing process when they are added during the compounding process. At the same time, to broaden the range of properties required to meet the demands of modern manufacturing, raw rubber is combined with an appropriate range and quantity of additives such as plasticizers, antioxidants and anti-ozonants, and functional fillers and pigments. The amount of additives introduced in compounding varies from just 2%–3% by weight for simple rubber bands to more than 60% for some highly specialized and sophisticated rubber products. The resulting compound, then, is unvulcanized rubber based on a particular formulation or "recipe" of rubber and compounding ingredients. Additives introduced in compounding are classified into the following categories:

- **Curatives:** Active chemicals that bring about the cross-linking of the long-chain rubber polymer (vulcanization). Sulfur is the traditional curative.
- **Accelerators and activators:** Chemicals such as zinc oxide that vary the speed and timing of the curing reaction.
- **Plasticizers:** Chemicals added to aid processability or to produce specified properties.
- **Antioxidants/antiozonants:** Chemicals added to help the compound resist surface attack, especially by ozone.

- **Process aids:** Substances that include resins, soaps, and low-weight polyethylene.
- **Reinforcing fillers:** Materials that increase the strength of the material. Carbon black and specialty silicas are the most common.
- **Fillers:** Relatively inert ground minerals used to increase the bulk of the compound. Ground calcium carbonate (GCC) and kaolin are the most common.
- **Pigments:** Minerals and chemicals added to produce specified colors. Only used with compounds that do not contain carbon black.

Curing or Vulcanization

Back in 1839, Charles Goodyear in the United States and Thomas Hancock in England found that heating a mixture of natural rubber and sulfur to 130°–140°C formed an elastic, nonsticky material with good mechanical strength that was insoluble in all solvents and did not soften further when heated. This process turned out to be the cross-linking of polymer molecules (i.e., the process in which the entangled chains are chemically linked together to form a network) known as curing, or, in more picturesque terminology, hot vulcanization. In the curing process, the compound is transformed from a plastic to elastic state, accompanied by the modification of the physicomaterial properties of the cured or vulcanized material. In particular, the product exhibits increased strength and elasticity and greater resistance to changes in temperature. At the same time, vulcanized rubber is impermeable to gases; resistant to abrasion, chemical action, heat, and electricity; and exhibits high frictional resistance on dry surfaces and low frictional resistance on water-wet surfaces (this in turn led to the invention of the pneumatic tire in 1877).

Subsequently, cold vulcanization (at room temperature) in the presence of sulfur chloride (S_2Cl_2) was discovered, along with a range of other chemical vulcanizing agents that can irreversibly

convert raw rubber from a plastic into an elastic material. These agents include selenium, tellurium, nitroderivatives, peroxides and hydroperoxides, diazoderivatives, or organometallic compounds, oxides, and modified phenol-formaldehyde resins. These vulcanizing agents have specific applications so that sulfur is a vulcanizing agent for natural rubber, polybutadiene, and butadiene-styrene copolymers, but it is not required in the vulcanization of polychloroprene or some specialty elastomers.

In the common hot vulcanizing process the vulcanizing agent is ground and mixed with the rubber and other dry ingredients; the proportion of sulfur to rubber varies from 1:40 in soft rubber goods to as much as 1:1 in hard rubber. In addition, most rubber products can be vulcanized under high temperature and pressure, often during the molding process. In some cases, the high pressures necessary for effective vulcanization are achieved by subjecting the rubber to external or internal steam pressure during heating (for example, garden hose may be clamped into shape and vulcanized by passing high-pressure steam through the opening).

Modern rubber curing systems vary both with the polymer type and with the property requirements of a particular application. Although native sulfur was the original curing agent, it now has a variety of competitors, including other forms of sulfur, peroxides, metal oxides, amines, and phenolic resins. In addition to the wide range of rubbers now in use, the rubber manufacturer has to deal with prevulcanization inhibitors (PVI) and antireversion chemicals.

Sulfur is the traditional and main vulcanizing agent. Utilization is mainly in the form of rubbermaker's sulfur, which is ground sulfur available in a range of purity with a uniform small particle size, generally in the range of 44–74 μm . Coarsely ground grades tend to be less dusty; finely ground grades have dispersion advantages. Additives may be included—for example, up to 2.5% of a conditioning agent may be added to improve flowability, handling, and dispersion characteristics of finely ground sulfur, and between 0.5% and 1.0% oil may be added as a dust suppressant to reduce the risk of a sulfur dust explosion. In cold vulcanization of soft, thin rubber goods such as gloves and sheeting, however, vulcanization is accomplished by exposing the uncured articles to the vapor of S_2Cl_2 manufactured by heating molten sulfur and chlorine gas to 240°C, followed by distillative purification.

Compounds that contain sulfur in a heat-labile form are used because they liberate sulfur at the vulcanization temperature. These so-called sulfur donors are subdivided into those that (1) exhibit an accelerator activity and can be substituted directly for sulfur without drastic change of the vulcanization characteristics [dithiodimorpholine, DTDM(I), and caprolactamdisulfide CLD(II)], and (2) are simultaneously vulcanization accelerators [2-morpholino-dithio-benzothiazole, MBSS (III); dipentamethylene thiuramtetrasulfide, DPTT(IV); and tetramethyl thiuramdisulfide, TMTD(VI)].

Accelerators and Activators

On its own, sulfur is a slow vulcanizing agent and increasing the amount of sulfur, temperature, and heating periods generates cross-linking inefficiencies. But through his research on rubber recycling in the early part of the twentieth century, the American chemist George Oenslager discovered that adding certain organic chemicals such as aniline and thiocarbanilide reduced the curing time and cut back on the oxidative degradation of the elastomers during vulcanization, thus improving the properties of the products or *vulcanizates*. Initially, these so-called vulcanization accelerators were confined to metallic oxides such as white lead and lime but they have since been expanded to include five major categories: guanidines, thiazoles, dithiocarbamates, xanthates, and thiurams. Of these, the guanidine-

type accelerators give the lowest rate of vulcanization as well as a relatively slow onset of vulcanization (scorch).

In general, these organic accelerators require activators to increase the efficiency of the accelerators by increasing the vulcanizing rate, reducing the vulcanization temperature, and improving the mechanical properties of the vulcanizates. Zinc oxide (ZnO) or zinc white is a popular and efficient activator because it leads to a decrease of the sulfidic cross-links while encouraging the formation of C–C bonds. The formation of these bonds in turn increases the thermal stability of vulcanizates. The very fine grades of zinc oxide in use contain a minimum of 99.5% ZnO and process a high surface area.

Product is manufactured by one of three processes: (1) the American process, where zinc oxide is obtained from the direct smelting of zinc ingot and the resulting zinc fumes are oxidized; (2) the French (or indirect) process, where zinc ash or dross is produced and sulfuric acid is used to vaporize it to zinc fumes that are then oxidized; and (3) the wet process, using precipitation from a carefully purified zinc-salt solution. In addition to activating sulfur cures, when dispersed into latex emulsion compounds, zinc oxide acts as a cross-linking agent for polymers containing halogen or carboxyl groups, such as chloroprene rubber (CR), brominated isobutylene-isoprene rubber (BIIR), chlorinated isobutylene-isoprene rubber (CIIR) or carboxylated nitrile butadiene rubber (XNBR), and carboxylated styrene-butadiene rubber (XSBR). Zinc oxide also has some pigmenting qualities.

Other compounds used as activators in rubber vulcanization are

- Magnesium oxide (MgO), which is mainly used with neoprene-type elastomers
- Litharge (PbO), which is less popular but still used along with thiazole-, dithiocarbamate- or thiuram sulfide-type accelerators
- Fatty acids, used as such or as zinc salts; these also improve the dispersion of zinc oxide. Examples include stearic acid, oleic acid, and dibutyl ammonium oleate.

Vulcanization Inhibitors/Scorch Retarders

Vulcanization inhibitors or scorch retarders such as MgO, salicylic acid, benzoic acid, acetylsalicylic acid, phthalic anhydride, N-nitroso-diphenylamine, or stearic acid are used to prevent premature vulcanization or scorching during processing. The concept is that the addition of a scorch retarder in the concentration range of 0.2%–1.0% extends the scorching period without decreasing the rate of the vulcanization process. This is particularly applicable where high-efficiency accelerators trigger the vulcanization process prematurely during processing; that is, mixing, preheating, extrusion, and calendaring (for the most part, scorching occurs during extrusion or in inner mixers where temperatures exceed 100°C).

Caustic calcined magnesia formed at 700°–1,000°C is chemically active and functions as an acid acceptor, vulcanizing agent, stabilizer, and curing agent in a variety of rubber and elastomeric compounds including neoprene, hypalon, natural rubber, styrene-butadiene rubber, viton, butyl rubber, chlorobutyl rubber, and fluoroelastomers. In addition, micronized, high-activity grades are used as scorch retarders in chloroprene and fluoroelastomers. Moderate-activity MgO is a scorch retarder and acid acceptor in diamine-cure fluoroelastomers.

Processing Aids

Processing aids used in the manufacture of rubber include plasticizers or softeners, antioxidants and antiozonants (antidegradants), and tackifiers.

Because the mixing of rubber compounds requires considerable energy, plasticizers or softeners are used to lower viscosity and thus reduce the energy required in fabrication. At the same time, these plasticizers—divided into chemical peptizers and physical plasticizers—may increase processing speed by improving melt stability. Typically added at 1–3 parts phr (by weight per hundred rubber), chemical peptizers such as sulfonic acids and pentachlorothiophenol reduce molecular weight by increasing the rate of oxidative chain scission. These chemical peptizers are used in the initial grinding or mastication of natural rubber. Physical plasticizers such as animal and vegetable oils, wool grease, fish oil, pine tar, and soya oil act to soften a compound by reducing entanglements and decreasing internal friction.

Other processing aids include mica used as a mold lubricant; magnesium sulfate used as a coagulating agent; ammonia used to prevent the coagulation of raw latex; salt to promote coagulation in emulsified latex derived from chlorinated butadiene and used in the production of neoprene, white, and buna rubber; and carbon disulfide (CS₂), used as a solubilizer.

Oxygen and ozone can react with elastomers and alter network structure by causing chain scission and/or cross-linking. Antioxidants and antiozonants inhibit the action of the degradants (and are therefore termed antidegradants) through a chemical or physical process. Chemical protectants such as amines, phenolics, and phosphites react with the degradant or interfere with the chain of reactions that causes degradation. Physical protectants such as various waxes function by migrating (i.e., blooming), thus forming a barrier to degradant attack.

Tackifiers are materials added to elastomers to improve tack; that is, the ability of two materials to resist separation after being in contact for a short time under light pressure. The function of tackifiers such as rosin derivatives that are typically added in the range of 1–10 phr is to increase initial tack and to prevent tack degradation after a stock has been processed.

Reinforcing Fillers

Reinforcing fillers increase the stiffness of unvulcanized compounds and improve a variety of vulcanizate properties such as tensile strength, abrasion resistance, and tear resistance. At the same time, stress values and hardness may be increased while elongation at break, rebound, and other properties (depending on the property) are lowered. A reinforcing filler has the ability to change the viscosity of a compound and the vulcanizate properties with an increasing amount of filler loading, whereas a nonreinforcing or nonactive filler such as GCC or kaolin (see section on Nonreinforcing Fillers in this chapter) slightly increases the viscosity of the compound and actually diminishes the mechanical properties of the vulcanizate.

To add significant reinforcement, filler particles must be of a small particle size (less than 1 mm), which generates a large surface area that can interact with the rubber and diminish particle-to-particle distance. At the same time, structure (irregularity in the shape of filler particles) and surface chemistry of the filler are critical because the extent and type of interaction between the filler and the rubber depends on functional groups on the filler surface. A filler with high structure has a large “void volume” within its structure, allowing rubber molecules to become “occluded.” This results in an occluded rubber-filler microcomposite that effectively becomes the reinforcing entity. Generally, high structure and strong bonding between the filler and the rubber increase reinforcement.

The two main commercial reinforcing fillers are carbon black and silica. Carbon black has an organic surface chemistry that makes the interaction between carbon black and the elastomer possible. In

contrast, silica has an inorganic surface chemistry that lacks a good interaction with the elastomer; therefore, silica fillers may be treated with silane coupling agents to chemically bond them to rubber. These fillers are available with a primary particle size as low as 100 Å.

Carbon Black

The traditional reinforcing filler in modern industrial rubber and tire manufacture has been carbon black, an intensely black, finely divided form of amorphous carbon in the form of spheres and their fused aggregates with sizes below 1,000 nm. This product is usually obtained by decomposing a hydrocarbon feedstock under precisely controlled conditions. For example, oil is heated above 2,000°F in a specially designed furnace where it “cracks,” producing a gas stream laden with carbon black powder. The gas stream passes through a series of filters, where the carbon black is separated as a powder, bound with water to create larger beads or granules, and dried. There are more than 100 commercial grades of carbon black characterized by spherical particles ranging from 10 to 100 nm that agglomerate into powders, pellets, and dispersions.

An estimated 70% of the world’s consumption of carbon black is used in the production of tires and tire products for automobiles and other vehicles, with an additional 20% going into sundry rubber products such as hoses, belting, mechanical and molded goods, and footwear. In general, carbon black accounts for about one quarter of the weight of a standard automobile tire. Tires used on vehicles requiring minimum electrostatic buildup, such as oil trucks and hospital operating carts, have even higher loadings. Nonrubber uses include plastics, ink, paper, and paint.

Precipitated Silica

Traditionally, precipitated silicas are used as reinforcement fillers in rubber applications. These products are made from a mixture of sodium silicate, sulfuric or hydrochloric acid, and metallic ions agitated to form precipitated silica with high brightness (97%), a 20-nm average particle size, and low porosity. Precipitated silica’s ultimate fine particle size generates a high surface area (25–700 m²/g) that allows for interaction with polymer chains. Precipitated silica is physically reactive when dispersed in silicone rubber, forming physical bonds with the polymer chains to enhance the vulcanized compound’s properties.

The rubber industry is the largest single consumer of precipitated silica, with the bulk used in the manufacture of tires plus a variety of industries including aerospace, appliances, medical, transportation, construction, electrical, and electronics. Rhône-Poulenc and Michelin pioneered the development of the so-called “green” tire in which between 5% and 25% of the carbon black is replaced with a highly dispersible silica (HDS, sometimes called “white carbon”) together with a bonding agent, usually a sulfur-bearing silane (i.e., silica-silane). The use of precipitated silica in the manufacture of tires as well as other technical rubber goods is based on the strengthening properties of silica, which provide tear and wear resistance. In tire manufacture, precipitated silica is used to

- Promote adhesion between brass-coated wire and fabric cord
- Alter stiffness in the bead area and thus increase the structural integrity of tires
- Reduce the tendency for “chunk out” of off-road tire treads through improved compound tear resistance (the chemical nature of the lattice structure is such that silica increases the energy required to propagate the tear, so adding 5%–8% silica increases the tear strength by 25%)
- Improve rolling resistance, wet traction, and other dynamic properties

It is claimed that green tires improve fuel efficiency by 5%–8% by reducing rolling resistance by up to 30%, compared with conventional tires filled with carbon black. This efficiency is achieved without sacrificing tread life, traction, or other properties. Silica-silane, however, costs approximately three times as much as carbon black, and there are increased compounding and processing costs. In addition, green tires tend to generate static buildup, although this can be countered through compounding and engineering modifications.

In the footwear industry, reinforcing silicas increases abrasion resistance and tear strength in rubber footwear and shoe soles. Because it is white, precipitated silica allows the formulator to produce either colored or translucent nonmarking soles. The silica provides superior durability and resilience while improving compound stiffness and modulus for all types of rubber-soled footwear. In industrial rubber, precipitated silica confers superior strength and durability on industrial belts and hoses, together with improved heat resistance and tear strength. The filler also improves adhesion in wire and fabric coat compounds and allows for rapid and easy processing, resulting in smooth finished surfaces in molded and extruded products.

In a related use, precipitated silica is used as a carrier to convert, for example, liquid plasticizers, process oils, and other rubber compounding ingredients to free-flowing powders for introduction into rubber compounds. This provides consistent loading performance and high absorption capability, making precipitated silica a more cost-effective carrier than mined products such as diatomaceous-earth-based calcium silicate.

Fumed (Pyrogenic) Silica

Formed from the hydrolysis of silicon tetrachloride in a hydrogen/oxygen flame reactor at 1,000°C, fumed or “pyrogenic” silica is a fine, particulate, amorphous silica composed of 7- to 20-nm spherical particles. This structure provides a high surface-area-to-volume ratio, and close control of the process parameters allows for the production of a number of grades that have specific particle sizes and particle-size distributions. Fumed silica is used for thickening, viscosity control, thixotropy, and reinforcement purposes in the rubber and other industries. For example, a loading of 6%–12% in silicone rubber products improves the mechanical strength of footwear, and 0.25%–3.00% in latex rubber increases the tear resistance of gloves, condoms, and the like.

Asbestos

In some asbestos paper, group 7 asbestos that is fiber coated with latex rubber via a chemical precipitation method forms a continuous sheet on a paper machine. This may be used as an underlayment for vinyl rolled floor covering or it can be densified for gasketing. Group 4 to 5 asbestos fiber blended with natural or synthetic rubber, plasticizers, and other ingredients in a high-shear mixer may be calendered to form sheet packing.

Nonreinforcing Fillers

The main nonreinforcing mineral fillers used in the modern rubber industry include the following:

- GCC and precipitated calcium carbonate (PCC)
- Kaolin and special clays
- Talc
- Mica
- Wollastonite
- Natural silica

- Barite and barium chemicals
- A variety of minerals such as diatomite, feldspar, nepheline syenite, gypsum, pyrophyllite, and zeolites

In addition to the minerals, oil extension of rubber, especially in tire treads, is common. Oil levels of 30–40 phr permit the use of elastomers with higher molecular weight and higher filler levels than would otherwise be possible.

Calcium Carbonate

Generally regarded as the most common and cheapest white mineral filler, GCC is used to reduce the cost of production. Dolomite may also be used and is preferred in certain circumstances, such as when there is a need for greater abrasion resistance. Ultrafine PCC adds strength without stiffness; acts as a white pigment; and generates smooth extrusions for wire and cable coating, footwear, and sporting goods.

Clays

Air-floated kaolin is a common function filler used in rubber products. This clay is processed dry simply by crushing, drying, and pulverizing, as well as by air flotation where kaolin is pulverized and separated from its abrasive “grit” mineral impurities on a moving column of air. Processing does not improve brightness and whiteness nor make significant improvements to particle size. Water-washed grades of kaolin are suited for extrusions where a low grit content is important and calcined kaolin is used in making heavy-duty insulation rubber. Overall, kaolin helps to stiffen uncured rubber and reinforce cured rubber, improving resistance to abrasion and tear and tensile strength, as well as to increasing the stiffness of the vulcanizate. The amount of reinforcement increases with smaller particle sizes of the filler so that the main characteristic of filler used as a reinforcement agent is a small particle size. There is a general division into hard kaolin used in nonblack rubber goods where high abrasion resistance is important, such as in shoe heels and soles, floor tiles and mats, wire and cable insulation, conveyor belts, and bicycle tires; and soft kaolin used in molded goods such as household products, toys, and rubber clothing.

Micronized sepiolite is a reinforcing filler in rubber compounds and acts as a processing aid by avoiding deformities during rubber extrusion when the rubber is in the green state.

Barite

Fine-grained (virtually all passing 325 mesh) barite is used as a filler in rubber and other products such as brake linings and clutch facings. As a functional filler, barite is white and relatively bright, chemically inert, relatively nonabrasive, resists weathering, has low oil absorption, and is dense. Related products are *blanc fixe* (reprecipitated chemically pure barium sulfate [BaSO₄]) and lithopone (a blend of 70% BaSO₄ and 30% zinc sulfide).

Barite is used as a filler in certain rubber products that must be weighty (automobile mud flaps, floor mats, rollers and their coverings, traffic cones) and/or chemically resistant (tank linings, industrial belts and hoses), or to impart sound-deadening qualities (insulation in automobile engine compartments). Rubber and rubber-covered rollers are used in numerous industries including paper, steel, textile, leather, and lithography, as well as for pressure functions such as inking or wringing and in typewriter platens. Loadings with barite may be around 20% by weight.

Silica

Silica sand ground to specific particle sizes forming ground silica or silica flour is used in certain rubber formulations, based on

whiteness, brightness of 84–91, hardness, inertness, low oil absorption, and low cost. Similarly, in the United States, tripoli (or the misnomer amorphous silica) is a friable microcrystalline silica with a natural average particle size of 0.1–0.5 μm . It is white (dry) to gray (wet) with an index of refraction of 1.550 and an oil adsorption (rubout method) of 17%–20%, making it useful as a filler in rubber and other products.

Other Fillers

Other functional fillers in the rubber industry include diatomite, talc, pyrophyllite, mica, wollastonite, nepheline syenite, and magnesite.

Diatomite's brightness of up to 90%, refractive index of 1.42–1.49, low bulk density, inertness, moderate refractoriness (softening range 1,400°–1,600°C), high absorptive capacity, and high surface area allow it to be used as a functional filler in rubber.

Talc is an extremely soft, nonabrasive, inert mineral that can be ground easily to form a low-cost, white and bright (>78 GE brightness), fine to micronized powder that acts as a white functional filler in rubber including carpet backing, valve rubber, and cable insulation. Additional advantages include its flaky habit (which allows for the ease of grinding), structural strength, pigmentation, opacity, rheology, viscosity, corrosion weathering resistance, and enhanced thermal properties. In addition, talc is used as a dusting agent and as a mold release agent for wires, cables, and in tire manufacture where it acts as a processing aid that lubricates molds and prevents surfaces from sticking together.

Pyrophyllite may be sufficiently white to be finely ground and used as a filler in certain rubbers. Agalmatolite, mainly produced in Brazil, is white, cream, or gray to greenish in color; is chemically inert; and has a brightness of up to 95%, a specific gravity of 2.7–3.0, and Mohs hardness of 2.5–3.0. These properties make it a useful filler in rubber.

Wet-ground and micronized mica in the 90- to 45- μm range retains its characteristic laminar crystalline structure. It is used as a specialized filler in rubber, as an antisticking and antifriction powder between the inner tube and casing of tires, and as a dusting agent and mold lubricant in rubber.

Wollastonite is used as a functional filler based on its acicularity, high brightness (90%–93%), chemical inertness, pH of 9.9, thermal stability and high melting point (1,540°C), good electrical insulation, and low moisture and oil absorption. It is particularly useful for increasing resistance to abrasion.

Nepheline syenite is used as a filler for improving resistance to staining, abrasion, and chemical attack, plus it has a high brightness and low tint strength and exhibits low viscosity at high pigment loadings. Specific examples of its use include silicone rubber automobile parts and neoprene rubber gaskets. It is categorized as generally recognized as safe (GRAS) for indirect food contact.

Ground natural magnesite and synthetic magnesium carbonate (MgCO_3) are white, relatively soft, and chemically inert powders used as fillers/pigments in rubber.

Fire Retardants

A number of minerals and chemicals used as fillers in rubber also serve as a flame retardant, smoke suppressant, afterglow suppressant, and/or antiarc/antitracking agent. For example, aluminum trihydrate or ATH [$\text{Al}(\text{OH})_3$], is a bright white powder produced as a by-product of the Bayer alumina process. ATH may be dried in hot air to form a white, bright, fine, and platy powder with good oil and water absorption properties and the ability to absorb UV light. Boron compounds melt during a fire to form a glass char barrier between oxygen and the burning surface. For example, zinc borate

($2\text{ZnO} \cdot 3\text{B}_2\text{O}_3 \cdot 3.5\text{H}_2\text{O}$; trade name Firebrake ZB) is a leading fire retardant for interior uses such as carpet backing and exterior uses such as wire and cable covering.

Antimony oxide acts as the synergistic agent with halogens (chlorine and bromine), forming halogenated compounds with excellent fireproofing and fire-retardant properties with rubber and other products. Antimony oxide alone is not a fire retardant and the halogens are weak fire retardants, but a combination of approximately 3–4 parts of halogenated flame retardants to 1 part of antimony oxide on a weight basis generates a synergistic and extremely effective flame-retardant system for plastics. Styrene butadiene rubber, ethylene propylene rubber, and other elastomers can be flame retarded with halogenated compounds and 5%–30% antimony oxide. Polyurethane is flame retarded with a brominated hydrocarbon and up to 10% antimony oxide.

Pigments

Certain minerals and chemicals are added to rubber compounds that do not contain carbon black to produce specified colors. Most of the white functional fillers outlined previously—titanium dioxide, iron oxide, zinc oxide, lithopone, and a number of organic dyes, for example—are also pigments.

Titanium dioxide is regarded as the premier white pigment based on its high refractive index of 2.55–2.80, which provides good opacifying strength or hiding power, and its reflectivity, which generates brightness and whiteness (or “lightening power”). Other attributes include inertness and nontoxicity, chemical stability, resistance to UV degradation (color retention), tinting strength, and thermal stability over a wide range of temperatures.

Natural and synthetic iron oxides can be used as a pigment in rubber. Natural hematite, Fe_2O_3 , is a brown to red earthy mineral that is ground to a low-cost red pigment used in rubber. Natural reds such as Spanish, Indian, or Persian red, the most common of the iron oxide pigments, contain about 50% iron oxide as hematite with tinting strength increasing with $\alpha\text{-Fe}_2\text{O}_3$ content (up to 95%). Compared with natural iron oxides, synthetic iron oxide has superior uniformity, color purity (i.e., chroma), tinting strength, and tighter control over color consistency. Synthetics are used in rubber because the manganese content of naturals accelerates aging.

Chromic oxide green, a dark-green powder consisting of about 99% chromic oxide mixed with small amounts of cobalt oxide, is the most stable green pigment known, with strong resistance to light, heat, acids, and alkalis.

Forming

After compounding, the rubber may undergo calendering where it is squeezed between rollers, forming sheets of the desired thickness, with or without impressed designs such as tire-tread markings. Some times “blanks” are cut from the sheet, like pasty cutting. Alternatively, the warmed rubber compound may be squeezed or extruded through a shaped die to form flat, tubular, or specially shaped pieces such as window and door sealers. Any reasonable length of shaped material can be produced and fed, once cooled, into direct injection presses. At the same time, rubber can form a coating on fabric and be molded.

In contrast, foam rubber is manufactured directly from latex by mixing in emulsified compounding ingredients and whipping mechanically in a frothing machine to produce a foam comprising millions of air bubbles. The foam is poured into molds and vulcanized by heating to form mattresses, seat cushions, and so forth. In addition, latex toys or gloves may be manufactured by dipping porcelain or plaster-of-paris forms into concentrated latex that adheres to the form and is stripped off after vulcanization.

The basic processes of molding are compression, transfer injection, and direct injection. In compression molding, uncured rubber of a given size is placed between two halves of a heated mold that is closed in a press under a pressure of about 1 st/sq in. and the rubber is forced into the exact shape of the cavity. The rubber gains heat by conduction from the mold surfaces and, given sufficient time, “cures.” This is a relatively simple process used for components with simple shapes required in fairly low quantities. Some secondary finishing is required, however, to remove the flash or excess rubber formed by the blank in a process known as “deflashing.” In transfer injection, the heated mold is closed in a press and the rubber injected by a hydraulic cylinder through a feed hole in the cavity that has a means to allow air to escape. This method yields high-precision parts produced in moderate quantities without high tooling costs. In the simplest case, the mold can be the same as a compression mold with the addition of a feed hole. With direct injection, a screw injection system delivers a metered quantity of rubber into the closed mold from a continuous strip or a reservoir of uncured rubber, then is cooled to a void premature curing. This process, which is utilized for multicavity molds, can produce hundreds of components per press cycle, and is also suitable for relatively large quantities of products that have a large number of cavities and infrequent changes of materials or molds. Parts are repeatable and can be made to a high level of precision.

Finishing

Where necessary, the method of deflashing depends on the shape and size of the component and the type of rubber used. For example, in subzero finishing that uses modern cryogenics, parts are frozen to temperatures as low as -120°C and then tumbled and/or bead-blasted to remove the brittle flash. In tear finishing, the system is set to produce flash sufficiently thin to be torn off at the press during demolding. Hand-finishing includes buffing, in which the parts are smoothed using a variety of abrasive belts, wheels, and mops; and cutting, in which a range of tools from precision steel knives to scissors are used to die-cut parts.

PROPERTIES OF RUBBER

Although most commercial applications of rubber are based on the ability to provide elastic properties across a wide range of temperatures, the combination of various types of rubber and compounding gives a diversity of properties:

- Utilization over a temperature range from -80°C to $+300^{\circ}\text{C}$
- Availability in a wide range of colors
- Electrically insulating, conductive, or antistatic
- Withstands extremes of weather and outdoor environments indefinitely
- Withstands exposure to fuels, oils, and chemicals while retaining its properties
- Ability to be rendered flame-retardant and self-extinguishing, with halogen-free and smoke-suppressant types available
- Maintains tension and compression forces indefinitely; e.g., in seals
- Conformable, adaptable, and accommodating of movement, shock, thermal changes, tolerances, and roughness
- Absorbs vibration and noise and acts as an insulator
- Can be gas tight and used as a fluid seal or separator
- Possesses low thermal conductivity and can be used to reduce heat transfer
- Friction properties similar to human skin and comfortable to grip

- Surface may be clean and smooth, which is nonstick and suitable for hygienic applications
- Compatibility with other engineering materials such as metals, plastics, and ceramics, and can be combined with these through bonding.

USES

Although native South Americans used rubber before the Spaniards arrived, the first widespread commercial application was the opening of a waterproof cloth and rainproof garment plant in Glasgow in 1823 by the British inventor and chemist Charles Macintosh; hence the name for the practical garments. Since then, the types of rubber and compounds have increased dramatically along with the range of everyday applications. At one end, resistance to abrasion makes softer types of rubber ideal for the treads of vehicle tires and conveyor belts. At the other, hard rubber may be used for pump housings and piping where abrasion could be problematic. Rubber's flexibility is applicable to hoses, tires, and rollers, and its elasticity translates into shock absorbers and machinery mountings designed to reduce vibration. Because it is relatively impermeable to gases, rubber is used to manufacture air hoses, balloons, balls, and cushions; and its resistance to water and to the action of most fluid chemicals is utilized in everything from rainwear and wet suits to flexible tubing and tank lining. Electrical resistance allows soft rubber to be used in protective gloves, shoes, and blankets, and hard rubber to be used in various parts in electrical instruments. Rubber's coefficient of friction, which is high on dry surfaces and low on wet surfaces, leads to its use both for power-transmission belting and for water-lubricated bearings in deep-well pumps.

Tires

The feedstock for tire manufacturing may include up to 30 different kinds of rubber, plus process oils, carbon black, pigments, antioxidants, accelerators, and other additives. This is mixed in giant blenders called Banbury machines that operate under tremendous heat and pressure to form a hot, black, gummy compound. This compound, in addition to cord fabrics and bead wire, is shaped and cured in a curing press at $>300^{\circ}\text{F}$ for 12 to 25 minutes depending on size. According to Goodyear Tire and Rubber Company, a P195/75R14 all-season passenger tire, the most popular size, weighs about 21 lb and is composed of the following approximate amounts of these materials:

- 4 lb of eight types of natural rubber
- 5 lb of eight types of carbon black
- 1 lb of steel cord for belts
- 1 lb of polyester and nylon
- 1 lb of steel bead wire
- 3 lb of forty kinds of chemicals, waxes, oils, pigments, etc.
- 6 lb of five types of synthetic rubber

Typical percentages of synthetic rubber and natural rubber in various types of tires, respectively, are 55% and 45% in passenger tires, 50% and 50% in light-truck tires, 65% and 35% in racing tires, and 20% and 80% in off-highway (giant/earthmover) tires.

Rubber Production

Modern natural rubber production can be traced back to 1876 when the British explorer Sir Henry Wickham smuggled seeds of *H. brasiliensis* out of Brazil, successfully germinated them in the hot-houses of the Royal Botanical Gardens in London, and established plantations in Ceylon (now Sri Lanka). Subsequently, the British developed commercial rubber plantations within a narrow equatorial

belt in the eastern hemisphere. Natural rubber production in India, Ceylon, the Malay Peninsula and Archipelago (now Malaysia), and the Dutch East Indies (now Indonesia) peaked prior to World War II, when supply was halted. The resulting shortage encouraged the development and use of synthetic rubber, which had previously been restricted to specialty use because of the high price. In particular, the U.S. government launched a \$700 million program in the 1940s to establish synthetic-rubber production plants that succeeded in, among other things, bringing the price of synthetic rubber down to that of natural rubber. Since that time, synthetic rubber production has increased rapidly, becoming the dominant form of rubber currently manufactured.

Synthetic rubber was developed in Germany during the 1930s in order to make up for a deficiency of supply of natural rubber and for natural rubber's functional defects. The United States was cut off from virtually all sources of natural rubber in the Pacific during World War II. To meet the nation's needs for this vital material, the government built synthetic-rubber production plants and the rubber industry operated them. Synthetic rubber production jumped from 8,000 t in 1941 to 820,000 t in 1945. After the war, the government sold the plants to private industry.

World rubber consumption is approximately 20 Mt, more than three quarters of which is synthetic. The vehicle sector (tires together with components) uses about 70%–75% of all rubber. The tire industry is estimated to grow at a slightly slower pace than other rubber industries. Globally, most rubber products are consumed in North America, Western Europe, and Japan. The growth rate, however, is faster in China and other countries in the Asia-Pacific area.

Synthetic rubber comprises about 60% of the total volumes. Approximately 44% of synthetic rubber and 77% of natural rubber are consumed by the tire industry (see Table 2). Of synthetic rubber types, styrene-butadiene rubber is used the most. Ethylene propylene diene, however, has a faster growth rate. The fastest growing demand is experienced by thermoplastic elastomers, which are materials with properties falling between those of traditional rubbers and thermoplastics.

GOVERNMENT, ENVIRONMENT, AND HEALTH

Rubber and the products used to manufacture it have come under intense scrutiny by regulatory authorities because of concerns about potential environmental and health effects. The increasing use of precipitated and other forms of silica in rubber brings up the usual concerns about silicosis. Zinc compounds, considered harmful to aquatic environments, could be released in the effluent generated during the manufacturing process, through wear (especially tires), by extraction from rubber products in contact with water such as pipe seals or faucet washers, or after disposal in landfills. The problem is that elimination would require a change in rubber vulcanization technology and the substitutes (lead, cadmium, and mercury) are unacceptable.

There are increasing government-imposed restrictions on the use of volatile organic compounds (VOCs) in the rubber industry and in other industries that make use of a large quantity of solvents. For example, a European Union (EU) Directive on solvent emissions adopted in March 1999 aims to reduce VOC emissions throughout Europe by 1.5 Mtpy. The main use of VOCs is for rubber-to-metal bonding, including metal cleaning and solvent-based adhesives. These are being replaced, however, by aqueous adhesives that may include silane-coupling agents for specific assemblies.

Another problematic ingredient is the distillate of aromatic extracts (DAE) that are used as extenders and softeners in rubber compounding. These oils contain relatively high levels of poly-

Table 2. North American tire sales

cyclic aromatic hydrocarbons (PAHs), and some are classified as a Category 2 carcinogen by the EU Dangerous Substances Directive. These must be labeled R45, "may cause cancer." Manufacturers (especially of tires) are under increasing pressure to eliminate DAE from their products.

TRENDS AND OPPORTUNITIES

World rubber consumption is forecast to reach more than 21 Mt by 2006, with tire production reaching 1.3 billion units based on strong gains in the global vehicle industry combined with replacement needs within a steadily rising global motor vehicle inventory. Traditionally, growth in rubber consumption has been driven by the automobile industry, with production concentrated in industrialized regions such as North America, Western Europe, and Japan. These regions should experience modest growth, however, as manufacturing expands in Asia and to a lesser extent in Africa, the Middle East, Eastern Europe, and Latin America. Automobile output in Asia reached almost 22 million units in 2003 or some 36% of worldwide production. The top five automobile-manufacturing countries in Asia—Japan, China, South Korea, India, and Thailand—account for 90% of total region production capacity with future growth expected to be largely centered in China, Thailand, and Vietnam.

The need to improve fuel consumption rates may encourage the use of precipitated silica in OEM tires. Replacement tires, however, do not have to comply with Corporate Average Fuel Economy (CAFE) standards and the like, a fact that may dampen the increased use of precipitated silica in aftermarket tires. Historically, many aftermarket tires were retreads, but because modern tires are so light and thin-bodied, retreading has decreased greatly in the passenger-tire market. At the same time, tire rubber demand will benefit from the continuing popularity of performance tires and sport utility vehicles in many developed countries, raising the amount of rubber incorporated into new tires and vehicles. Performance tires also have shorter service lives relative to all-season radials, thus stimulating replacement demand.

According to the Freedonia Group, the nontire rubber market will grow to become the dominant market for rubber by about 2006. This growth will be driven by increased demand for mid-range elastomers (e.g., ethylene-propylene, nitrile, and polychloroprene) in numerous types of industrial rubber products such as hoses, belts, gaskets, and weatherstripping.

Filters and Process Aids

Sharad Mathur and SA. Ravishankar

Process aids enable the desired results from a process to be achieved. The filtration process, for example, uses filters to remove dissolved and particulate matter from suspension to purify, clarify, and clean liquids. Absorbents are a convenient way to handle liquids and to clean up liquid wastes or spills. Rheological modifiers change the flow behavior of formulations such as paints, cosmetics, and inks. Lubricants allow for mold detachment that results in smooth surface finish. Binders are process aids that improve mechanical integrity of beads to enable better flow, for example. Finally, proppants are beads that help create and keep open the cracks caused in oil and natural gas bearing rocks to allow access to these raw materials from the surface.

The underlying phenomenon behind the action of the various process aids can be either chemical action or mechanical action or both. Mechanical action is derived from physical properties of the particles, such as size, size distribution, shape, surface area, and hardness, whereas chemical action is derived from surface chemical properties that are either native to the material or modified in a controlled manner. Filtration or absorptive processes are accomplished either mechanically, as in absorption and filtration, or chemically, as in adsorption. Rheology modifiers typically use both the chemical and mechanical forces.

Table 1 shows a number of processes, end-use applications, and minerals and rocks that are used as process aids.

This chapter focuses on the industrial minerals and rocks used as process aids for filtration, absorbents, rheology modification, and proppants. The selection of the minerals and markets reviewed was based solely on the total volume of material used or the value of the market and material. The materials include diatomite, perlite, sand, gravel, glauconite; specialty clays such as kaolinite, montmorillonite, and attapulgite; and their modified forms such as activated montmorillonite or surface-treated montmorillonite and kaolinite. Throughout this chapter the term *specialty clays* is used to describe clays used in such value-added markets.

RAW MATERIALS

On a volume basis, the most common industrial minerals and rocks—sand and gravel, along with diatomite—are used as filters and absorbents. High-quality sand finds more value when used as proppants. High value-added applications such as pet litter absorbents and edible and inedible oils filtration and clarification use specialty clays.

Table 1. End-use applications, processes, and the minerals and rocks that are used as process aids

Process	End-Use Application	Process Aid
Filtration	Liquid food products	Perlite
		Diatomite
	Water treatment	Perlite
		Diatomite
		Glauconite
	Petroleum and chemicals	Perlite
Absorption	Pharmaceuticals and drugs	Diatomite
		Perlite
		Diatomite
	Pet litter	Perlite, diatomite, attapulgite
	Oils and grease spills	Attapulgite
	Pesticides and fertilizers	Attapulgite
Rheology modification	Plastics	Montmorillonite, kaolin
	Paints	Attapulgite, kaolin
	Paper coatings	Bentonite
	Inks	Kaolin
Pressurization (proppants)	Petroleum and natural gas	Sand, kaolin, bauxite
Binding		Attapulgite
Lubrication		Attapulgite

MINERALOGY

The common mineralogical trait of almost all industrial minerals used as process aids is that they belong to the silicate group. Silicates have an inherent chemical stability, unique molecular structures, and surface activity that can be used as is or modified for a given application. These characteristics enable the silicates to be used as process aids. Silica (SiO_2), the common chemical constituent, exists by itself in nature as an inert crystalline form as quartz or in an amorphous form such as diatomite. The fundamental building block of both forms is the SiO_4 tetrahedra. By combining with other chemical groups and rearranging the SiO_4 tetrahedra, a multitude of silicates, including specialty clays, are obtained in nature with varying physical and chemical properties.

Table 2. Classification of the major specialty clays used as process aids

Clay Group/Principal Mineral	Synonymous Term	Theoretical Chemical Formula
Smectite (three-layer structure)		
Montmorillonite	Bentonite (fuller's earth)	$(\text{OH})_4\text{M}^{+0.66}\text{Si}_8(\text{Al}_{3.3}\bullet[\text{Mg}_{3.3}\text{ to Na}_{0.66}])\text{O}_{20} + \text{H}_2\text{O}$
Calcium montmorillonite	Nonswelling bentonite	Same formula as montmorillonite where M^+ is generally Ca^{2+}
Sodium montmorillonite	Swelling bentonite	Same formula as montmorillonite where M^+ is generally Na^+
Lithium	Hectorite	$(\text{OH})_4\text{Si}_8(\text{Mg}_{5.34}\bullet[\text{Li}_{0.66}\text{ to Na}_{0.66}])\text{O}_{20}$
Hormite (chain structure)		
Palygorskite	Attapulgite (fuller's earth)	$(\text{OH}_2)_4(\text{OH})_2\text{Mg}_5\text{Si}_8\text{O}_{20}\bullet 4\text{H}_2\text{O}$
Sepiolite		$\text{H}_6\text{Mg}_8\text{Si}_{12}\text{O}_{30}(\text{OH})_{10}\bullet 6\text{H}_2\text{O}$
Kaolin (two-layer structure)		
Kaolinite	Kaolin	$\text{Al}_4(\text{Si}_4\text{O}_{10})(\text{OH})_8$

Diatomite and Perlite

Although the mineralogy and origin of diatomite and perlite are very different, they have a physical trait in common that yields excellent filtration properties: both have cell structures that form microscopic voids, which aid in filtering by allowing the passage of fluids while retaining the solid particulate matter.

Diatomite is a chalk-like, soft, friable, earthy, very fine-grained, siliceous sedimentary rock, usually light in color. Diatomaceous silica is the preferred name for the principal mineral component. It is the fossilized skeletal remains of the diatom—a unicellular, microscopic aquatic plant related to algae (Kadey 1983). The silica of the fossilized diatom skeleton closely resembles opal or hydrous silica and has the chemical formulation $\text{SiO}_2 \cdot n\text{H}_2\text{O}$.

Naturally occurring perlite, on the other hand, is a dense, amorphous, hydrated (2% to 6% combined water) volcanic glass, generally of rhyolitic composition. It has a dual nomenclature in the industry because of its commercial applications. It is known by the same name as both the naturally occurring rock and, after processing and thermal expansion, as the lightweight aggregate (Kadey 1983).

Specialty Clays

Compared to other minerals used as process aids, the clay minerals are much more mineralogically complex. As a general definition, clays are naturally occurring, earthy, fine-grained hydrous silicates (Patterson and Murray 1983). Collectively, they are classified as phyllosilicates, a group of silicate minerals characterized by silica-oxygen tetrahedra linked together in two-dimensional sheets (Thrush 1968). Their uses in value-added applications may require extensive beneficiation to improve purity and control physical characteristics. Montmorillonite and attapulgite are known by their mineral name for the raw material as well as the final product. Montmorillonite is the principal mineral constituent of bentonite, and the two terms are used synonymously in the industry. Kaolinite, on the other hand, is known by the ore-body name kaolin for the end-use product.

The phyllosilicate group of clays consists of several minerals, each having different geologic occurrence, mineralogy, technology to beneficiate and engineer to its final form, and uses. The three major clay mineral groups, which account for the majority of the volume of clays used as process aids, are the smectite, hormite, and halloysite clay groups. Table 2 lists these clay groups, commonly used names, and mineralogical compositions. Although the mineralogy is complex, it is easier to think of these minerals as containing crystal structures that can be broken down into two simple building blocks: tetrahedra and octahedra. These building blocks form sheets or layers by joining at the corners (tetrahedra) or at the edges (octahedra) (Moll and Goss 1987), as shown in Figures 1 and 2.

Given these basic building blocks, the distinguishing structural difference between the different types of specialty clays is the arrangement of these blocks to generate layered and chain types of silicates.

Smectite Group

Two members of the smectite group, montmorillonite and hectorite, are used as process aids. Smectite minerals have a three-layer structure. Two outer layers of silica tetrahedra are attached to a central octahedral layer of hydrous metal oxide (usually aluminum, sodium, magnesium, calcium, or lithium). The layers are combined

in such a way that the oxygen atoms at the tips of the tetrahedra of each silica layer are shared with the octahedral metal oxide/hydroxide layer. A small proportion of the metal cations in the central octahedral layer is replaced by cations of lower valence but similar size. This leads to an electrical charge imbalance that is corrected by the presence of cations held outside and between each of the three-layer units. The electrical charge deficiency of the three-layer units and the presence of the exchangeable cations (commonly sodium or calcium) impart the characteristic expansion properties to the smectite group of clays (Clarke 1985).

Palygorskite and Sepiolite (Hormite) Group

Palygorskite (attapulgite), which is used primarily as an absorbent, is based on the hormite group. Sepiolite, a related mineral, is also used to a limited extent. Hormites are markedly different in terms of their structural characteristics in that they form chain-type rather than layered structures, which result in a fibrous morphology (Clarke 1985). Unlike the smectite minerals, which have sheets that extend laterally, the sheets in hormite minerals extend only a short distance and then flip up or flip down in a continuous pattern to yield a three-dimensional structure that includes long tubes instead of layers. Because of this structure, hormite minerals do not swell as do smectite minerals. Crystal lattice substitutions, or exchange capacity, however, do occur at the broken bonds on the edges of the crystal (Moll and Goss 1987).

Kaolin Group

Kaolin is the principal industrial mineral used as a process aid based on this group. This group consists of minerals that form a two-layer structure. The two layers comprise tetrahedral and octahedral sheets. The tetrahedra contain silicon and oxygen and the octahedra contain aluminum, oxygen, and hydroxyl, arranged in sheets (Figures 1 and 2). The apices of the tetrahedra join with the octahedra to form the two-layer structure with water molecules between the two layers. These sheets generally are neutral, except on the edges where broken bonds create unbalanced charges. These sites are areas where cation exchange can occur (Moll and Goss 1987).

Sand and Gravel

In the strictest sense, these two materials are defined by size rather than by composition or mineralogical makeup. Sand and gravel consist of separate grains or particles of detrital rock with a particular size range of $1/16$ to 2 mm in diameter. For filtration and proppant applications, however, sand consists mainly of pure, rounded quartz (SiO_2) grains (Davis and Tepordei 1985), and gravel typically consists of rock fragments.

Glaucanite

Glaucanite is a hydrous iron potassium silicate containing varying amounts of aluminum, calcium, magnesium, sodium, and numerous trace elements such as beryllium, cobalt, chromium, nickel, molybdenum, vanadium, titanium, and uranium. It has the chemical formula $3X_2(\text{Fe}^{+3}, \text{Fe}^{+2}, \text{Y})_6(\text{Si}_4\text{O}_{10})(\text{OH})_4 \cdot n\text{H}_2\text{O}$, where X is K^+ , Na^+ , or Ca^{+2} , and Y is Al or Mg. Its exchangeable sites are on the outside of the silica–alumina–iron framework, and the exchange reaction generally does not affect the glaucanite structure. Both cations and anions are exchangeable, but little information is available on the latter (Spoljaric 1994).

Minor Minerals

Other minerals used as process aids include vermiculite, talc, ball clay, bauxite, crushed limestone, gypsum, ilmenite, and garnet. Vermiculite, talc, and ball clay are also in the phyllosilicate group.

As a consequence, these minerals, especially vermiculite, are commonly used in certain absorbent applications. Such heavy minerals as garnet and ilmenite (and sometimes anthracite coal) are often used as filter media in wastewater treatment plants. Calcium carbonate (especially as lime) and gypsum are two nonsilicate minerals that find limited applications as filters, absorbents, and rheology modifiers. Bauxite is used as the raw material to produce superior-performing proppants to sand.

CHEMICAL AND PHYSICAL PROPERTIES

Silica or silicon dioxide, the main constituent of process aids, is responsible for their chemical stability. Physical characteristics such as high amount of porosity resulting from micropores allow for efficient filtration and absorbent materials. Good mineral filters and absorbents thus are chemically stable and have high porosity that allows liquids to either flow through or be retained in the structure. In addition to immobilizing the water, high aspect ratios of specialty clay particles such as needle-like (attapulgite) or plates (montmorillonite) play a critical role in modifying rheology of suspensions and pastes. Chemical modification of montmorillonites to result in an organoclay or acid-activated form enables application as rheology modifiers and sorbents, respectively. Round-grain deposits of high-purity sand are used to maximize the permeability and strength for proppant application. Thus it is not surprising that the minerals used as process aids in a given application have a number of similar chemical and physical properties. Table 3 shows chemical analyses of the major materials used as process aids.

Diatomite and Perlite

Minerals used as filtration aids typically are lightweight, structurally rigid, chemically stable, and chemically inert, and they form high-porosity filter cakes to maintain free flow of the liquid. Both diatomite and perlite have such characteristics. The major differences between these minerals, however, are in density and flow rate. Perlite is typically less dense or weighs less per unit of volume and thus yields additional filtering capacity per unit weight (Van Kouteren 1994).

Diatomite

The diatom structure, which provides high surface area, low-bulk density (floating on water at least until saturated), high absorptive capacity, and relatively low abrasion, consists of openings or pores at regular intervals, which in turn result in a very open lattice (Kadey 1983). The pore structure can account for about 50% of the volume of a diatom, which is typically only a few micrometers in thickness and 50 to 150 nm in diameter (Miles 1990).

Perlite

Perlite is known for its unique internal cellular structure, which forms on heating and subsequent expansion. The integrity of the cellular structure is dependent on the source rock. Hard perlites, which have coarse cell walls, are relatively dense and thus are typically used as aggregate. Soft perlites, which have finer cell walls and are less dense, are typically used as filtration aids (Kadey 1983).

Specialty Clays

The layer and chain structures, combined with cation-exchange characteristics, are responsible for specialty clays' unique chemical and physical properties. Clays are platy, are extremely fine grained, have flexible crystals with large surface areas, are naturally reactive, and have a house-of-cards structure (Moll 1986). During heating and the subsequent release of water, the clay's structure maintains its integrity. Structural integrity is responsible for the

clay's low bulk density, high liquid-holding capacity, and high absorptivity (Moll and Goss 1987).

Glauconite

Glauconite grains range in size from 1 mm (coarse sand) to the sub-micron and develop different shapes. The largest percentage by weight is 0.49 to 0.125 mm in size. Grains are usually smooth and round. Like other layer minerals, glauconite has the capacity to absorb ions from solution. Ion exchange is important in chemical separations, water softening, and the properties of soil for both agriculture and engineering (Spoljaric 1994).

Sand and Gravel

The important chemical and physical characteristics of sand and gravel used as filters are chemical inertness and proper particle shape and size. As filter media, the removal of particulate matter is a function of both media size and filter bed depth. Optimal packing of sand grains, which are supported by the gravel, occurs in filtration applications when a high proportion of the sand particles are rounded and tend toward a generally spherical or equidimensional shape (AWWA 2002). When used as proppants, the sand has tighter requirements for its physical characteristics.

DISTRIBUTION OF MAJOR DEPOSITS

United States

The United States contains major deposits of all the industrial minerals and rocks used as filters and absorbents. In fact, the diatomite, kaolin, attapulgite, and sand deposits are world class in terms of size and purity. These deposits, however, occur in select areas of the country. Diatomite and perlite deposits are in the West, the specialty clay deposits are in the South, and sand and gravel deposits occur in all regions. The biggest disadvantage in regard to deposit location and market demand is that diatomite and perlite are mined

in the West and the demand is concentrated in the Midwest and the East.

Diatomite and Perlite

All of the commercial deposits of diatomite and perlite occur in the western United States. Diatomite is currently mined in California, Oregon, Washington, and Nevada. California and Nevada are the principal producing states; they accounted for 79% of U.S. production in 2002 (Dolley 2004).

New Mexico accounts for the majority of perlite mined in the United States, with the remaining portions mined in Arizona, California, Colorado, Idaho, and Nevada. Given that expanded perlite has a very low bulk density and that the majority of perlite is consumed in the East, crushed perlite ore is typically transported to expander plants, which are located close to major end-use markets (Meisinger 1988).

Specialty Clays

Commercial deposits of nonswelling or calcium montmorillonites are, for the most part, in Texas, Mississippi, and Alabama, which account for the majority of calcium montmorillonite. The swelling or sodium montmorillonite deposits are primarily in Wyoming, South Dakota, and Montana. Florida and Georgia account for all the attapulgite production. Sepiolite primarily occurs in Nevada. Hectorite is mined in California and Nevada. Georgia accounts for a majority of high-class deposits of kaolin.

Glauconite

The most important glauconitic greensands are developed in the Mid-Atlantic Coastal Plain. Glauconite is found as an accessory mineral in many coastal plain sediments of New Jersey, Delaware, and Maryland, but highly glauconitic greensand is best developed in Upper Cretaceous and Lower Tertiary formations.

* Water permeability flow ratio (basis: Grefco's Dicalite 215 as 100).

Sand and Gravel

The occurrence of sand and gravel deposits is pervasive throughout the United States. From a strictly geologic view, the quantity of sand and gravel is essentially inexhaustible (Dunn 1983). Although this is true for gravel used in filtration, it is not true for sand. The sand used in filtration and proppant applications has rigid specifications as to the purity, size, and shape of the individual grains. As a consequence, the major deposits that naturally yield such material are limited to locations in northern Illinois and central Texas (Van Kouteren 1994).

Other Parts of the World

A review of the U.S. Bureau of Mines mineral production statistics indicates that no one country dominates in producing materials used as filters and absorbents. A number of countries, however, are major producers of these raw materials.

Diatomite and Perlite

The production of filter-grade diatomite in the rest of the world is concentrated mainly in such European countries as France, Spain, and Germany. Korea, Romania, and the former U.S.S.R. are all large producers, but they are believed to have very limited, if any, production of filter grades. For perlite, nearly 80% of the production outside the United States is concentrated in Hungary, Greece, Turkey, and the former U.S.S.R. Perlite production has increased significantly in Greece at the expense of western states in the United States. Several developmental projects are under way in China and other Asian countries (Barker, Santini, and Alatorre 2003).

Specialty Clays

Production of specialty clays occurs mainly in Brazil, Canada, and Mexico. Europe and the Pacific Rim are also major producing areas, with Germany, Greece, Italy, Japan, Malaysia, and Turkey accounting for most of the production.

Glaucanite

Glaucanitic greensands are developed on all continents and have been geologically mapped in many countries. At some locations, glaucanite is the most abundant constituent of the formation. In most cases, however, it is present in relatively small amounts or as a minor component of the sediment (Spoljaric 1994).

Sand and Gravel

Given that the geologic occurrence of sand and gravel deposits is pervasive, sand suitable for filtration applications exists in many countries. The location and production of sand from these deposits are closely correlated to the location of population and industrialized areas (Bolen 1988).

TECHNOLOGY

Processing and Specifications

Diatomite and Perlite

The most important processing aspect for these materials is maintaining the integrity of the diatom cell walls and the expanded perlite cellular structure. After processing, these materials are subjected to filtration tests that measure flow rate through a filter cake under controlled conditions and the clarity of the resulting filtrate (Kadey 1983). Because of the difference in physical structures of perlite and diatomite, their performance varies from one grade to another. Table 4 lists the performance and specifications for these materials.

Diatomite. The degree of processing is highly dependent on the desired physical and chemical properties needed by the end-use industry. Depending on the desired filtration flow rates, diatomite is sold in three different forms: natural, calcined, and flux calcined. The natural products have the higher densities, smaller median pore sizes, and lower flow rates. Calcination of natural products yields less dense, larger median particle sizes, and, consequently, higher flow rates (Van Kouteren 1994).

Diatomite cannot be subjected to intense crushing or grinding; thus, it is crushed in spiked rolls and hammer mills, passed through air cyclones, and then fed to air separators to yield various sizes (Miles 1990). Material at this stage is classified as natural diatomite. For faster flow rates, the natural material is heated in rotary calciners to burn away both organic residues and the combined water that is part of the opaline structure. As a result, the diatom structure shrinks and hardens, and many of the diatom fragments are sintered into agglomerates (Kadey 1983). This heating process yields calcined products, which are usually for medium flow rate grades and typically are pink because of the oxidation of iron during the heating.

Filtration applications that cannot tolerate the presence of iron oxide or applications that require faster flow rates use flux-calcined diatomite products (Anon. 1987). These products are formed by adding a flux, usually soda ash or sodium chloride, before the sintering or calcination stage. The flux allows iron oxides to enter a glassy phase in which it is colorless and produces greater agglomeration of the diatom fragments. Variations in the kiln temperature, the amount and composition of the flux, and the heating time in the kiln enable suppliers to create products with differing filtration rates (Miles 1990).

Perlite. Perlite is used in its expanded form in filtration applications. The application for which it is intended plays a major role in the particle size range into which the material must be crushed and sized before expansion. Crude perlite ore is crushed with jaw crushers and impact milling and then sent to vibratory screening and air classification to separate the milled material into basic

grades. The size range of the expanded perlite dictates the size of the furnace feed (Kadey 1983).

During heating, perlite particles reach a softening range, coincident with the volatilization of combined water at about 800°C. As a result, the particles can expand or pop in a manner similar to popcorn with the creation of countless tiny bubbles. The lightweight cellular aggregate that forms is 20 times or more the original volume of perlite. During the heating process, a good balance between the softening of the glass and the volatilization of the combined water must be maintained. If not, excess combined water will cause some perlites to explode with the subsequent production of fines. In contrast, insufficient water or an overly viscous glass will result in partially expanded, higher density perlite (Kadey 1983).

On expansion, the perlite is then milled and classified to a specified size and density. The perlite bubble aggregates must be broken into curved glass platelets and bubble junctions. Filter aids require the right proportion of these with a minimum of unmilled cells. Residual unmilled cells, or floaters, are undesirable in filter applications (Kadey 1983).

Specialty Clays

The processing of specialty clays for use in absorbent applications is fairly similar for attapulgite, hectorite, and montmorillonite. Because clay ore may contain up to 60% water, the main objective for processing is to remove water and to reduce the material to the appropriate size. Before the crude clay is dried, it must first be passed through shredders to reduce it to fist-sized pieces for feed to a dryer (Moll 1986).

Proper drying techniques are essential for developing and maintaining the open structure in montmorillonite and attapulgite. Between 100° and 200°C, water in the interlayer region of montmorillonite or in the tubes of attapulgite begins to evaporate. At higher temperatures, certain tightly bound water molecules in attapulgite begin to evaporate. Between 500° and 800°C, the hydroxyl ions begin to combine to form water, which leaves the structure (Moll and Goss 1987).

Once the clay is dried, the material is typically crushed in corrugated roller or hammer mills and passed over large shaking screens. Oversize material goes back to the crushers, and undersized material goes to the next set of smaller sized screens to make products of increasingly smaller granule sizes. These smaller products are typically destined for the pet litter and floor absorbents markets (Moll 1986).

Kaolin is processed either in a dry state (air-float grades) or in a slurry state (water-washed grades). The water-washed grades are

extensively beneficiated and thus contain less impurity, have higher degree of whiteness, are less abrasive, and have tight control on particle size distribution. Hydrous kaolin can be heated to eliminate the hydroxyls from the structure and thus resulting in calcined grades.

Absorbents. The key properties for clays used as floor absorbents are proper granule size, low bulk density, the ability of the product to absorb liquids readily and rapidly, and durability so that the granules do not break down in normal shipment and use (see Table 5). Floor absorbents, mainly used for oil and grease, are sold in sizes ranging from 4.00 to 0.43 mm. The other key properties typically are a bulk density of about 625 kg/m³ and the ability to absorb about 65% to 100% of their weight in water or oil (Moll 1986).

In cat litter, the pH and the granule size are the important factors that affect the clay's performance. Low-pH products are more effective in controlling the fermentation of urea in cat urine. The size of clay granules is important so as to avoid dustiness in use and to avoid tracking by the cat. A common size range for cat litter products is often 4.75 to 0.60 mm (Van Kouteren 1994).

Carriers. Specialty clays used in pesticide, fertilizer, and other carrier applications often require further drying. Products that do not undergo additional heating, called regular volatile material (RVM), are typically softer and dispersible in water. Low volatile material (LVM), however, undergoes additional heating to result in a moisture content of less than 3% compared to 7% in RVM products (Ross 1983). These products tend to be harder and far less dispersible in water because of the tightening of the interlocking crystals of the clay caused by further heating (Moll and Goss 1987).

Another key property is surface acidity, also known as Lewis acidity. The surface acidity of the clay granules can degrade some chemicals absorbed into the granule. To prevent the degradation, formulators must measure the strength of the Lewis acid sites to determine how much deactivation is required. High surface acidity clays, measured by the Hammett acidity function unit (pK_a), are deactivated with alcohols or glycols to neutralize the acid sites (Moll and Goss 1987). Table 6 gives examples of the important end uses for carrier minerals.

Filtering and Clarifying. Acid-activated montmorillonite clays used for filtering and clarifying or bleaching vegetable and petroleum oils are an important part of the market. Although the tonnage of acid-activated clay is relatively small, it represents one of the highest value products.

Treating calcium montmorillonite clay with HCl or H₂SO₄ yields a modified clay product with significantly greater surface

area and acidity. The acid-activated clay offers enhanced absorptive and catalytic properties. These products, commonly called bleaching clays or bleaching earths, are not to be confused with fuller's earth, which is processed only by drying and grinding. Acid-activated clays are processed by predrying the clay to remove excess moisture. The material is then mixed with either HCl or H₂SO₄ to form a clay–water slurry that is then transferred to a reaction vessel. Once inside the vessel, it is heated to near boiling by steam or other means until the desired degree of activation has been achieved (Taylor and Jenkins 1986).

Generally, physical factors such as particle size and porosity along with surface acidity determine the suitability of a particular activated clay to perform in a particular environment. Small particles and larger pores are usually preferred when large molecules are involved (e.g., vegetable oils) and diffusivity limits transport of a molecule to an active site. Another consideration, more chemical than physical, is the strength of the acidity associated with the sorbent/catalyst. In some cases, excessive functionality may be detrimental. For example, strong acid sites can catalyze undesired reactions (e.g., disproportionation of toluene to benzene and xylene; Dombrowski and Henderson 1997).

Rheology Modification. Naturally occurring clay minerals such as hectorite and bentonite (sodium montmorillonite with some nonclay impurities) are hydrophilic in nature. When dispersed in water, the clay particles swell and separate into individual clay platelets. Because of platelet interaction, a three-dimensional “house of cards” structure is developed. This colloidal structure provides thickening properties. In oil or solvent systems, however, the natural clays do not disperse and do not provide rheological properties. To thicken oil and solvent systems, the hydrophilic clays are modified with various types of hydrophobic quaternary ammonium compounds. To make an organoclay, the smectite clay is reacted with a quaternary ammonium compound. The quaternary amine ion (Cl[−]) exchanges with the sodium cations on the surface of the clay. The resultant product is an organoclay, where the organic component is firmly bonded to the clay surface. During this reaction, the salt produced is washed out. Supplied as powders, the organoclays are in the form of agglomerated platelet stacks. A combination of wetting and mechanical energy is needed to deagglomerate these platelet stacks. Adding a polar group containing materials like low-molecular alcohols, water, or propylene carbonate help force the clay platelets further apart, resulting in a completely dispersed rheological structure (Braun and Rosen 2000).

In recent years, organoclay-type products have been improved to increase the ease of dispersability of these products. The new types of organoclays offer a more open structure compared to the conventional organoclays. The open structure helps dispersability of the product under low shear and short processing times and eliminates the milling stage of the ink manufacture. In most cases, the overall throughput is improved by reducing the production cost (Braun and Rosen 2000).

Glaucanite. Processing at Sewell, New Jersey, involves first screening crude, mine-run green sand. Approximately two thirds of the crude is recovered as −1.0+0.25 mm feed for the production of manganese greensand for use as a water filtration medium. Washing with water and chemical treatments with an intervening freshwater rinse cycle follows the screening to build a manganese dioxide coating on the glaucanite. This coating is the active agent in removal of iron, manganese, and hydrogen sulfide from well water. The coated glaucanite is dried and packed in 0.03-m³ bags or 1-t supersacks, palletized, and stretch-wrapped for shipment (Spoljaric 1994).

Table 6. End uses for industrial minerals and rocks used as filters and absorbents

Absorbents	Industrial
Hazardous wastes	Alginates
Oil and grease	Catalytic reactions (hydrogenation)
Pet litter	Cellulose liquors
Water	Electroplating
Waxes and varnishes	Dry cleaning
	Metalworking industries (coolants, cutting oils, etc.)
	Nonedible oils and greases
	Nylon and rayon liquids
	Soaps and glycerine
	Synthetic resins
	Varnishes and lacquers
Carriers	Metallurgy
Fertilizers	Cyanidation
Pesticides	Metal extraction (Be, W, others)
Chemicals	Recovery of metal values
Acids (sulfuric, phosphoric, organic)	Uranium processing
Dyestuffs and intermediates	
Inorganic-general	
Organic-general	
Solvents	
Sulfur	
Titanium pigments	
Desiccants	Petroleum
Documents	Contact filtration (clay removal)
Electronic packaging	Dewaxing
Equipment storage	Greases and lubricants
Food packaging	Hydraulic fluid
	Jet fuel
	Oil well pressurizing
	Petrochemical
	Still residues
	Used oils (crank case, transformers)
	Waxes
Drugs and Pharmaceuticals	Waste Disposal
Antibiotics	Paper mill effluents
Cosmetics	Sewage
Enzymes, serums, vitamins, etc.	Radioactive (underground injections)
Pharmaceuticals	Laundry waste waters
	Industrial wastes, general
Food Products	Waters
Beverages (beer, wine, whisky)	Industrial
Corn products (sugar, glucose, oil)	Military (potable, engine condensate)
Fruit products (apple, grape, citrus)	Municipal
Miscellaneous (casein, dairy products)	Super-clarified (electronics, beverages)
Oils and fats (vegetable, animal)	Swimming pools
Packing house products	
Sugars (cane, beet, plantation, etc.)	
Yeast	

Sand and Gravel

The mining and processing of sand and gravel vary considerably with the type of deposit and the physical and chemical requirements of the desired product. Gravels are typically quarried or dredged and processed by screening. Sand is typically hydraulically mined because of the friable nature of the deposits (Van Kouteren 1994). The sand slurry is purified in cyclones where clays and other impurities are removed. The material is then drained and placed into fluid-bed dryers. After drying, vibratory screens, gyratory screens, mechanical or air classifiers are used to yield various sizes and size distributions (Davis and Tepordei 1985).

The American Water Works Association (AWWA) has prepared standard specifications for sand and gravel to cover such water filtration applications as surface water, sewage disposal, industrial waste, and swimming pools. The main specifications include freedom from organic matter, silt, minerals that fracture or deteriorate,

and acid-soluble components, and minimum specific gravity requirements (Severinghaus 1983). Filter gravel should contain a high proportion of particles that are rounded and tend toward generally spherical or equidimensional shape. For sand, the grains must be rounded or angular, very durable, and have a uniformity coefficient of 1.7 or less. The required size of sand and gravel is a factor of the viscosity of the filtrate, the type of contaminant, and the flow rate desired. Sand size typically ranges from 0.35 to 0.65 mm and gravel ranges from 2 to more than 60 mm (AWWA 2002).

Proppants have the same requirements of sand as in filtration except that high purity and integrity is required to deliver crush resistance to high pressures present in the oil and gas wells up to 2,400 m deep.

TESTING

As is common with most industrial minerals, the testing procedures by which processed minerals and aggregates are evaluated and standardized are designed to quantify an attribute required in the performance of a product (Kadey 1983).

Filtration

The two important characteristics that filter aids must produce are clarity and flow rate. A filter aid grade, then, must be subjected to a filtration test under controlled conditions. The test will measure how efficient the filter aid is in obtaining the required clarity at a reasonable flow rate.

Diatomite and perlite suppliers provide such bench-scale pressure or vacuum filtration tests as the bomb filter, Buchner funnel, and Walton filter. These tests help to determine the best balance of variables to obtain required clarity, maximum throughput, and minimum filter aid dosage. Before laboratory filtration tests, materials are tested for such physical properties as particle- and pore-size distribution, turbidity, and surface area. Wet and dry bulk densities are also important because diatomite and perlite are purchased on a weight basis and used on a volume basis (Severinghaus 1983).

The use of sand and gravel in the filtration of surface and wastewaters requires tests for acid solubility, sand and gravel shape, specific gravity, and particle size to ensure proper quality. AWWA, the American National Standards Institute (ANSI), and the American Society for Testing and Materials (ASTM) have established standard tests for these properties. For details on the testing procedures, contact either AWWA or ASTM (AWWA 2002).

Absorbents

For absorbents, the important characteristics to measure include clay's ability to absorb liquids easily and quickly, to have a high liquid-holding capacity, to have granules that do not break down during shipment, and to have relatively low bulk densities. Standard tests and techniques to measure a granule's maximum absorption and resistance to attrition are outlined by federal specifications. In addition, agricultural carriers undergo a liquid-holding capacity test. The Rhone-Poulenc method MP-12 is a test that measures the amount of liquid the granules can absorb without sticking together (Moll 1986).

Particle-size distribution, surface and titratable acidity, concentration of minor components, moisture level, and degree of leaching are all properties that make one acid-activated clay different from another, and these nuances are major considerations in selection of the right grade (Dombrowski and Henderson 1997). In filtering and clarifying applications, the final color of the bleached oil is the critical property. Test methods for evaluating montmorillonite and other types of fuller's earth for bleaching edible oils are outlined in the American Oil Chemists' Society (AOCS) Official

Method Cc 8b-52 and AOCS Official Method Cc 8a-52 (Patterson and Murray 1983). These specifications contain instructions on bench-type tests, including stirring time, heating rates and temperatures, approved equipment, quantities of clay and raw oil required, and other items (Patterson and Murray 1983).

Rheology Modifiers

The selection of the rheological additive is dependent on the application as well as the composition of the formulation ingredients such as solvents, binders, extenders and pigments, and the nature of their interactions. The viscosity profile in Figure 3 illustrates the relationship between shear rate and other important properties of two different paint formulations. Settling, sag, and leveling occur at low to ultralow shear rates. Package appearance and stirred consistency are determined by rheological behavior at medium shear rates. Application usually occurs at high shear rates (Elementis 2002).

Viscometers with well-defined geometry such as capillary, cone and plate, coaxial cylinders, falling balls/needles/rods, or cup is used for testing rheology. A great range of such equipment was designed over the past several years. These range from equipment with well-defined geometries capable of providing shear stress data at well-defined shear rates to equipment without such capability. The former type is highly useful for measurement of Newtonian fluids as well as non-Newtonian types; the latter types are equally useful to the practical rheologist and for quality control. There are many situations where it is possible to obtain a reproducible set of numerical data that correlates with some critical aspect of product formulation, behavior, or control (Braun and Rosen 2000).

Proppants

The critical properties for sand, or bauxite- and kaolin-based beads, to be used as proppants are as follows:

- Size—coarser size is better to improve permeability but needs to be optimized to ensure that transportation is not prohibited.
- Shape—equidimensional shape is better to enable improved porosity and thus permeability and withstand load. Thus only Ottawa and Jordan sand are deemed fit for use as proppants.
- Concentration in the suspension—higher concentration results in improved permeability.
- Strength—higher strength allows for use in deeper wells.
- Density—for given concentration in the fracture, there is proportionate decrease in propped fracture width for a denser proppant.

USES

Industrial minerals and rocks are used in many process-related applications, as shown in Tables 1 and 6. On a tonnage basis, however, the majority of these minerals, including sand, diatomite, perlite, attapulgite, and montmorillonite, are used in such end uses as municipal waters, food products, chemicals, pet litter, oil and grease, and carriers.

Filtration

Filtration is commonly referred to as the separation of solid particulate matter from the solvent media via use of a porous medium. Minerals comprise only a small part of the total market for materials used in the filtration of liquids. Such materials as membranes, cartridges, fabrics, and centrifuges account for the majority of the materials (Rees 1990).

The main mechanisms of filtration that use minerals are depth filtration and cake filtration. In depth filtration, solids are trapped

Source: Elementis 2002.

Figure 3. Relationship between shear rate and other important properties of two different paint formulations

within the medium using such granular media as sand. In cake filtration, solids are separated from the liquid by forcing the liquid to flow through a porous medium, such as diatomite or perlite, and depositing the solids to form a filter cake (Thrush 1968).

Depth Filtration

The major applications that utilize depth filtration are municipal water facilities that process surface water and sewage. These consumers use sand, anthracite, and, occasionally, gravel to remove impurities from water and other liquids. Gravel, however, is generally used—primarily in water treatment facilities—as a support media for the filtration sand (Van Kouteren 1994).

In depth filtration, the filter media is the portion of the filter bed that removes particulate matter from the water. The removal of particulate matter is typically a function of both media size and filter bed depth, and removal generally improves with greater depth or smaller media size or both. Selecting filter bed depth and media size is typically a function of the raw water conditions, plant pretreatment facilities, and designer preference. Therefore, the bed depths, particle sizes, materials, and the number of mediums vary widely plant to plant (AWWA 2002).

Most sand filters, or single-medium filters, are horizontal beds of carefully graded grains beginning with coarse particles to form the bed and becoming progressively finer toward the top layer (Severinghaus 1983). For improved overall performance, dual- or multimedia filters have been used instead of single-medium filters in many water treatment applications, and in some cases high specific gravity filter media, usually garnet or ilmenite, are used to remove more suspended solids at higher filtration rates (AWWA 2002).

Cake Filtration

Cake filtration uses a filter aid that controls the flow and amount of solids removed from the liquid. Filter aids form a porous layer

known as the filter cake on the septum, which may be cloth, screen, porous stone, or metal. The filter cake on the septum traps solids from suspension and prevents them from blocking the septum.

Good filter aids require a suitable particle size and shape to achieve optimum cake permeability, particle retention on surface versus depth, minimum flow resistance, good cake release, and relatively low cost. Because cake filtration is a mechanical process, the structure of the particles must be such that they will not pack too closely. For example, diatomite's skeletal structure and irregular-shaped particles interlock to leave 85% to 95% voids. These voids form billions of microscopically fine interstices in which suspended particles can be trapped (Anon. 1991) and are responsible for filtration flow rate and the final filtrate clarity.

The selection of the proper grade of filter aid in cake filtration depends on the size of the suspended particles to be removed. As the particle size and thus the flow rate increase, the ability of the filter aid to remove small particles of suspended matter decreases. Conversely, as filter aid particle size and flow rate decrease, the ability of the filter aid to remove small particles of suspended matter increases (Kadey 1983).

The two major types of filters used to remove solids from food products, chemicals, petroleum, and drugs and pharmaceuticals are pressure filters and rotary filters. The most common types of pressure filters include horizontal tanks with rotating leaves, sluicing filters, tube or candle filters, horizontal plate filters, vertical tank or vertical leaf filters, and the filter press. Pressure filters are used for many different types of applications; for thick, difficult-to-filter liquids or when solids content is high, however, vacuum rotary filters are typically used.

Pressure Filtration. Filtration in a pressure filter is a two-stage operation. First, a thin protective layer of filter aid called the "precoat" is built up on the filter septum by recirculating a filter aid slurry. This slurry is either diatomite or perlite and the liquid. The mixture continues to circulate until the liquid becomes clear, which

is when a precoat bed about 2 mm thick has been established and filtration is ready to begin (Anon. 1985).

The next step is called the body feed because, as the liquid is pumped through the filter, small amounts of filter aid are constantly fed into the liquid. As filtering progresses, the filter aid mixed with the suspended solids from the unfiltered liquid is deposited on the precoat. Thus, a new filtering surface is continuously formed (Anon. 1985).

Body feed rate is increased or decreased depending on the turbidity of the unfiltered liquid. As filtration proceeds, the volume of the cake increases until the solids trapped in the bed cause the flow to drop to an unacceptable level or the pressure to increase to an unacceptable level. At the end of the cycle, the filter is opened, cake is removed from the septum, and a fresh precoat is established for another cycle (Anon. 1985).

Rotary Vacuum Precoat Filters. As mentioned previously, these filters are generally used only where a large percentage of suspended solids is to be removed. A rotary vacuum precoat filter consists of a horizontal drum, of which 30% to 50% is submerged in a filter bowl containing the unfiltered liquid. This drum is covered with a septum capable of retaining a filter aid. Vacuum is applied to the surface of the drum by means of internal piping (Anon. 1985).

In operation, a precoat of diatomite or perlite up to 150 mm thick is built up on the drum by revolving the drum under vacuum in a filter aid slurry. After the precoat is built up to the desired thickness, unfiltered liquid is introduced into the filter bowl. As the drum rotates, a blade running across the face of the drum above the liquid level continually advances toward the drum. This peels off the solids plus a very small amount of precoat, thereby presenting a new precoat surface for the next submergence. This continues until the knife is within 6 to 10 mm of the drum, at which time the drum is cleaned and precoated again (Anon. 1985).

Absorbents

Consumer

Specialty clays in the pet litter market have proved to be very effective in absorbing liquid pet waste and related odors. They can absorb large quantities of liquid cat waste and retard the formation of ammonia, which is created when urea from cat urine ferments (Harris and Eckert 1989).

Industrial

Any user of oil and grease or machinery requiring oil and grease may ultimately require specialty clays to absorb and control spills. Slippery films of oil and grease and puddles of water and other chemicals often create dangerous conditions on the floors of machinery repair shops, factories, service stations, and numerous large and small industrial facilities (Harris and Eckert 1989). Specialty clays can absorb up to their own weight in oil, grease, water, and a variety of other chemicals. The clays also are safe, absorb rapidly, and can be cleaned up with a broom or shovel (Moll 1986).

Carriers

Specialty clays used as mineral carriers have a wide variety of applications in the field of agricultural chemicals. Most pesticides, including herbicides, fungicides, and insecticides, are highly toxic and typically require only a kilogram per hectare (Moll 1986). The primary function of these carriers is therefore to dilute high-potency chemicals to a spreadable field concentration so that they can be applied to a location where the pest can be destroyed but

damage to desirable plants, wildlife, and the environment is minimized (Swayer 1983).

The two main types of mineral carriers are absorbent and non-absorbent. The absorbent carriers, which account for the majority of demand, provide a highly porous structure that accounts for their high absorptivity and low density. The nonabsorbent types provide only surface area to carry the chemicals and typically have high bulk densities, which limits the amount of chemicals they can carry. Montmorillonite, attapulgite, and diatomite are the absorbent carriers. Minerals such as ball clay, calcium carbonate, quartz sand, and talc are considered nonabsorbent (Moll and Goss 1987).

Clays are also used as anticaking additives in dry fertilizer mixes. The anticaking function of the clay works by coating fertilizer particles and absorbing solvents or water that may be present. This reduces the formation of crystals that often bind particles and cause caking problems (Harris and Eckert 1989).

Filtering and Clarifying

Acid-activated montmorillonite clays and attapulgite clays (also called bleaching clays or fuller's earth) are used to filter and clarify such liquids as edible and in edible oils, petroleum products, and beverages. Although filtration is a part of the process, selective adsorption plays a major role in clarifying these products. Bleaching or clarifying these products is necessary to remove organic pigments from plant oils, sulfur compounds from mineral oils, and contaminants from fuel and lubrication oils (Anon. 1968).

The two main methods used for commercial bleaching are contact and percolation. The contact process is commonly used in refining edible oils and consists of mixing clay (0.5% to 3.0%) with the crude oil and heating the slurry to about 80° to 120°C for about 15 min. The slurry of clay and oil is then filter-pressed to remove the clay (Anon. 1968).

The percolation method, which is also a filtration process, is generally used to clarify lubricating oils. Granular clay is placed in a column and oil is then trickled through the clay by way of gravity. To obtain maximum efficiency, the viscosity of the oil is lowered by heating or dilution. This allows the oil to penetrate the minute pores of the clay. At the end of the cycle, the clay is washed with naphtha, steamed, and burned in a rotary kiln to regenerate the adsorbent, which then can be reused (Anon. 1968).

Other Markets

The most significant other absorbent market for specialty clays is desiccants and catalysts. Clay desiccants are used to adsorb moisture from the air enclosed in such packaged products as military equipment and electronic components. This helps prevent corrosion of the product and retards the formation of mildew. The desiccants are calcium montmorillonite clays that are oven dried, crushed, and packaged in bags or canisters. These products are most effective in conditions of moderate relative humidity (15% to 40%) and are generally preferred because of their ability to adsorb more than 20% of their equivalent weight in water without any apparent change in size, shape, or texture. Furthermore, they are also available at a relatively low cost (Harris and Eckert 1989).

Acid-activated montmorillonite clays are unique in that these possess not only high solid acid properties but also regular pore openings of about 20 Å. This latter feature is not found on zeolites or molecular sieve catalysts. This combination permits acid-activated montmorillonite to be used in various catalyst applications such as manufacture of silicone oils used in sealants. Acid-activated montmorillonite is also used as a catalyst in esterification, dehydration, and alkylation processes (Dombrowski and Henderson 1997).

Rheology Modifiers

Specialty clay additives are added to formulations primarily for rheological control. Dispensing viscosity and flow properties can be customized by using one of these clay additives in a formulation. These products provide unique rheology without the ropiness or tackiness often encountered with gums or other thickeners. Associated functions of these clay additives are emulsion stabilization and solids suspension. These clay additives can also be used as carriers for therapeutic or medicinal compounds. A variety of clay additives provide virtually all water-based and solvent-based consumer products with unique rheological properties and superior stability.

Applications in personal care, cosmetics, and pharmaceuticals are numerous, for example, facial masks, color cosmetics, moisturizing lotions, medicated creams, hair conditioners, and sunscreens. The unique rheological properties provided by these clay additives are ideal for products that are applied topically. Applications in household, industrial, and institutional cleaners are also numerous. The specialty clay products can also be used to create formulations that adhere to surfaces with a minimum amount of dripping or sag. These products can be used in a wide pH range and are compatible with bleaches. Common applications in these areas include hard surface cleaners, toilet bowl cleaners, bleach cleaners, oven cleaners, metal polishes, and laundry products (Braun and Rosen 2000).

Organoclays, prepared by exchange of sodium ions of the montmorillonite with the organic compounds, are used in oil-based paints, in high-temperature grease, in oil-based drilling muds, and in inks (Braun and Rosen 2000).

Proppants

Hydraulic fracturing is a technique used to allow oil and natural gas to move more freely from the rock pores where they are trapped to a producing well that can bring them to the surface. The fracturing is accomplished by pumping a highly viscous fluid containing sand particles into the well bore. The extent of the fracture is controlled by the characteristics of the geologic formation, its depth, the fluid type, and pumping pressure. When the fracture reaches the shale above (or below) the geologic formation being fractured, it will stop; shale does not fracture easily. A hydraulically created fracture will always take the path of least resistance, which means staying within the formation that fractures most easily. Hydraulic fractures typically extend 250 to 750 ft from the wellbore. The fracture initiates from the wellbore and extends out in two wings in opposite directions. Therefore, the total distance of the fracture from tip to tip is 500 to 1,500 ft, with the wellbore located in the middle.

To carry sand horizontally for 250 to 750 ft, a viscous fluid is used to keep the proppant in suspension during its journey through the fracture. After the operator has completed the fracture job, the viscous fracturing fluid needs to be removed from the reservoir so that the oil or gas molecules can move easily through the fracture. After all, the operator doesn't want a thick fluid similar to instant pudding in the sandstone or coal reservoir; it would just block the pathways to the wellbore. With this in mind, fracture fluids are designed to "break down" after the job has been completed. The break-down technology has improved dramatically over the years. For example, when a predetermined amount of time passes after the fluid has been pumped, the viscous fluid begins to thin. Typically, the fluid will break down until it has the relative consistency of water, so it can easily pass through the propped fracture into the wellbore for production to the surface. The only substance intended to remain downhole is the sand proppant. The fluid used to carry the proppant is pumped into the well but then is recovered once the job is complete. The process of creating these fractures sounds complex, but, in reality, it relies on the laws of nature and takes

only a few hours. The actual time spent pumping fluid into the well depends on the formation, the fluid type, and the depth, but it can be as little as 30 min. The fluids themselves are the product of extensive research to develop the right combination of ingredients to efficiently create fractures, prop them open, then return the carrier fluid to the surface to open the way for oil or gas to flow. The appropriate fluid depends on the formation being fractured.

Hydraulic fracturing is a safe, effective, and valuable tool for increasing the recovery of oil or gas. Many oil and gas formations cannot be economically produced without fracturing. By creating a "highway" with a fracture, the hydrocarbon molecules are more inclined to "travel" to the wellbore, increasing production and helping oil and gas producers meet growing demands for energy (IOGCC 1999).

INDUSTRY STRUCTURE

As with most other mineral-based industries, the industry structure determines the competitive environment in which the seminal process aids are sold. The four major factors that determine the industry structure are

1. The concentration of the supply and the demand side of the business
2. The barriers to entry
3. The availability of substitutes or not-in-kind products that can compete on a cost performance basis
4. Deposit quality and technology with the existing suppliers

These major factors play a significant role in the profitability of suppliers of minerals and rocks to this industry.

Industry Concentration

Supply

Because of the limited number of high-quality deposits, a few suppliers control the supply of the minerals.

Diatomite and Perlite. The perlite industry in the United States is changing, and competition is increasing. U.S. production in 2003 was 512 kt, a fourth consecutive year of decreasing production from the record 711 kt in 1999. The economic downturn resulting in decreased consumption and the availability of cheaper imported perlite to the eastern and Gulf Coast states from Greece were the major reasons for the shortfall in production. In 2003, crude ore production in the United States came from 10 mines operated by eight companies in seven western states. Processed ore was expanded at 63 plants in 30 states, and 9% of processed perlite was sold as filter aids (Barker, Santini, and Alatorre 2003).

The United States is the world's largest producer and consumer of diatomite, which is primarily used for filtration. Diatomite production in the United States in 2003 was estimated to be 624 kt. Production came from seven companies with 12 processing facilities in four states, and 63% of finished product was used as filtration aids and 13% was used as absorbents. Diatomite filter aids have been used in about 200 locations throughout the United States to treat potable water. Celite, Eagle-Picher, and Oil-Dri are major producers of diatomite (Dolley 2004).

Specialty Clays. Specialty clay production in the United States is highly concentrated. The major producers of attapulgite are Oil-Dri (Zemex), Milwhite, Engelhard, and ITC (Kline & Company 2002). IMV Nevada is a supplier of sepiolite, a mineral similar to attapulgite and used in similar applications as attapulgite. American Colloid, BPM Minerals, and Black Hills Bentonite have similar market share of sorbent granular products based on bentonite (Landis 2004). Süd-Chemie, Laporte Inorganics, Engelhard, Mizusawa Industrial Chemicals, and Wembley Activated Clay are

major producers of activated bentonite (Dombrowski and Henderson 1997). R.T. Vanderbilt, Elementis, Sud Chemie, and Southern Clay Products are the major suppliers of bentonite used as rheological modifiers (Kline & Company 2002). For kaolin, the major producers are Engelhard, Imerys, J.M. Huber, and Thiele Kaolin.

Silica Sand. Although the supply of high-purity silica sand is also concentrated, it is much less so than diatomite, perlite, and the specialty clays. The top 7 to 10 companies that supply high-purity sand to the filtration industry are estimated to account for about 50% of the total sales. The major suppliers of these materials are Unimin, U.S. Silica, and Vulcan Materials (Van Kouteren 1994). Unimin, U.S. Silica, Oglebay Norton, Badger Mining Corporation, and Fairmount Minerals are the sand suppliers for the proppant application.

Glauconite. Glauconite production is concentrated in the coastal plain of New Jersey, where greensand is extracted from Cretaceous and Tertiary sediments. Inversand Co., a division of Hungerford & Terry, Inc., produces processed greensand, also called manganese greensand, in the United States.

Demand

On the demand side, the filtration industry is generally more concentrated than the absorbent industry.

Filtration. The demand side of the filtration market is highly concentrated. Beer brewing is considered the largest end-use application and on this basis the market can be considered to be highly concentrated. Five consumers account for about 80% to 85% of total diatomite and perlite use in such food product markets as soft drinks, juices, sugars, and beer. The concentration of consumers in the chemical, petroleum, and drugs and pharmaceutical industries is also high. Less concentrated filtration markets include industrial varnishes and lacquers, industrial water filtration, and dry cleaning. Another exception is the waste and surface water filtration market. The demand for sand and gravel in filtration is mainly from municipal water treatment plants, which exist in nearly every county in the United States.

There are two avenues of distribution for manganese greensand: dealers and original equipment manufacturers (OEMs). Dealers are primarily small- to medium-size water treatment companies that resell tanks, chemicals, and so forth, and provide service for domestic and other small water systems. OEMs design and manufacture equipment for large-scale municipal and industrial installations as well as smaller commercial and domestic systems, and service these water treatment facilities. They receive a small price incentive for making large, single orders and promoting the product. Many dealers are located in the midwestern United States. Large dealers in Europe distribute greensand from ports of entry in Sweden and Italy. Inversand Co. has also shipped greensand to Indonesia, South Korea, Trinidad, Chile, and Thailand in the past few years. A large manganese greensand water treatment system, possibly the largest ever, has been built in Saudi Arabia.

Absorbents. The demand side of the absorbent market is relatively unconcentrated. The pet litter and oil and grease markets consist of hundreds of brokers or wholesalers who purchase and distribute the clay products to thousands of retail stores. The carrier market is the only major end-use market for absorbent applications that is fairly concentrated: about 10 firms account for more than 50% of the demand for clays in this industry. The pet litter market could be considered highly concentrated with companies like Ralston Purina (Nestle) and Clorox controlling most of the major brands.

Rheology Modifiers. These modifiers are used in numerous applications in the personal care, cosmetics, household, and industrial markets.

Proppants. Three well services companies—Halliburton, M-I Drilling Fluids, Schlumberger, Ltd., and BJ Services—account for more than 90% of the global demand for proppants. The well services companies typically purchase the proppants and resell them to well owners as part of their well-fracturing service.

Barriers to Entry

Industry competition is also affected by the threat of new entrants. New entrants to an industry bring new capacity and the desire to gain market share; they also often add new resources, which can result in lower profitability. The threat of entry into an industry in part depends on the barriers to entry combined with expected reaction from existing competitors.

The major entry barriers for the materials used as filters, absorbents, rheology modifiers, and proppants are related to the availability and location of economical deposits and significant capital investment. The limited availability of high-grade deposits of diatomite, sand, and specialty clay materials is the most significant barrier to entry in this industry. New entrants into the specialty clay markets are probably further deterred by the need to have access to distribution channels for the pet litter and oil and grease markets. In addition, brand or brand name recognition is especially important in the pet litter market.

Not-in-Kind Materials

The availability of not-in-kind or substitute materials that are competitive on a cost-performance basis plays an important role in industry structure. Substitutes limit the potential returns of an industry by placing a ceiling on the prices that firms charge. A number of good organic and inorganic substitutes for filter and absorbent applications are being used in the market today. Such materials as synthetic fabrics, ground corncobs, paper-based product, cellulose products (wood based), and ground alfalfa play a role in the absorbent markets. A discussion of these materials and others, their markets, and performance is in the Economic Factors and Government Regulations section of this chapter. Rheology modifiers are being challenged by synthetic polymeric products such as carboxymethylcellulose (CMC), for example. In the proppants area, the need to dig to deeper levels for natural gas is shifting the material requirement and the market share from sand to higher performance ceramic proppants.

ECONOMIC FACTORS AND GOVERNMENT REGULATIONS

Costs

The major cost factor for mining, processing, and transporting industrial minerals and rocks used as filters and absorbents is typically the energy costs associated with drying and calcining. Mining costs are relatively low because material is mined in open pits and generally does not require blasting. Processing costs are high, however, because of the moisture content of these deposits, which is often in the 30% to 60% range (Miles 1990). The significant increase in the natural gas pricing (about three times from 1997 to 2004) with little or no gain in product pricing has strained the profitability of the industrial minerals.

The cost, on a tonnage basis, to transport filtration and absorbent raw materials to the market is typically higher than with other industrial minerals and rocks because of their low bulk densities. As a result, transportation costs are a significant portion of the total cost of the delivered product. This is especially true for diatomite and perlite because production is in the West and the major markets are east of the Mississippi River. Thus, because imports from Greece to the East Coast are cheaper, these imports are increasing. Furthermore, perlite must be shipped in a crude form to the major markets and then processed or expanded.

Table 7. Breakdown of demand for major industrial minerals used in filtration and absorbents markets (2003 USGS data), Mt

Mineral	Filtration	Absorbent, Pet Waste	Absorbent, Others
Bentonite (calcium and sodium)	127,000*	987,000	W†
Fuller's earth (montmorillonite and attapulgite)	66,200	2,400,000	353,000
Diatomite	425,290	65,890‡	
Perlite	59,600	NA§	NA

* Data for 2002.

† W = Withheld to protect company proprietary information.

‡ Includes both pet waste and other absorbents.

§ NA = Not applicable.

Another cost factor, although not directly related to mining, processing, and transporting products to the market, is disposal costs. Consumers of industrial minerals and rocks are facing increasing disposal costs for spent filter cakes and absorbent materials. The cost to transport the spent materials to an acceptable landfill, combined with the costs and liabilities of disposing the materials, is rapidly increasing. Also, clay absorbents cannot be incinerated because most incinerators do not run hot enough to disintegrate them. Thus nonclay absorbent usage is on the increase. A good example is oil spills on water. Clay absorbents will absorb the oil but quickly sink, carrying the pollution from the top of the water to the bottom. This market is now dominated by synthetics—which are treated to absorb only oil and not water—that float for gathering and then incineration.

Markets

Table 7 shows the breakdown of demand for the major industrial minerals used in the filtration and absorbent markets.

Sand and gravel used in the filtration application are typically the lowest priced materials whereas acid-activated clays are the most expensive. Attapulgite pricing can range up to \$400/t for some specialty applications, including cosmetics (T. Harris, personal communication). The acid-activated clays have the highest average price; however, the total demand for these clays is relatively minor (Van Kouteren 1994).

Filtration

The filter aid market is the single largest application for diatomite, accounting for 73% of total diatomite consumption in a given year (Kline & Company 2002). High-purity quartz sand, diatomite, and perlite accounted for the majority of the volume used in such major uses as wastewater, food products, and chemical industries. The wastewater markets account for the most tonnage because of the large volumes of municipal and industrial water and waste that require treatment. These applications use sand and gravel, along with anthracite and, in some cases, such high specific gravity minerals as garnet and ilmenite.

Absorbents

The cat litter and oil-specific filtration media markets generate \$1 billion each at the retail level; spill clean-up absorbents is estimated to be a yearly market approaching \$120 million (International Absorbents Inc. 2004). This includes both industrial minerals and not-in-kind products. Roskill (1997) estimated that the total world market for bentonite and allied clays in absorbent uses is between 4.3 and 4.5 Mt with modest annual growth. Bentonite's gain in the pet litter market since the mid-1980s has resulted from (1) clumping of its granules versus those of hornite clays, making it easier to remove soiled litter; (2) reduction in dispersal or "tracking" because

of its high density; (3) stronger and longer lasting granules; and (4) the presence of free silica in the form of cristobalite (considered harmless from a safety viewpoint) in sepiolite grades.

Although the volume of clays used in filtering and clarifying oils is only 4% of the total volume, these acid-activated clays account for nearly 15% of the total value.

Rheology Modifiers

The total demand for minerals used as rheology modifiers (including organoclays) in paint and health and personal care products was about 16 kt, valued at about \$81 million, in 2001 (Kline & Company 2002).

Proppants

The 2001 sales of sand in the proppant market are estimated to be \$150 million.

Substitute Materials

Until recently, the threat to minerals from substitute materials or alternative technologies was somewhat limited. Recent environmental and health regulations, however, combined with improvements in such alternative technologies as membrane or ultrafiltration, have and will continue to have an adverse impact on the demand for minerals.

Filtration

Competitive materials and alternative technologies are currently decreasing demand for diatomite and perlite. Perlite, a competitive material to diatomite in filter cake applications where clarity is not so critical, has gained market share in recent years. The rivalry between the use of diatomite and perlite has intensified because of regulations on crystalline silica as well as the growing volume of low-priced perlite imports. Some perlite suppliers have increased their marketing efforts to exploit the fact that perlite's crystalline silica content is much less than that of diatomite. As a result, perlite has made gains in such food product markets as juices (Rees 1990; Van Kouteren 1994).

Ultrafiltration technology or cross-flow membrane filtration uses pressure gradients, chemical and electrical potentials, and synthetic membranes to separate macromolecular and colloidal solutes or particles (Clark 1985). In recent years, this technology has gained market share in the food products, biomedicine, and biotechnology markets. The gain is due in part to the increasing disposal costs of spent diatomite and perlite filter cake. In addition, the cost to use this technology has decreased because of advances in membrane and equipment performance and durability (Rees 1990).

Unusually high levels of dissolved iron in water are commonly caused by low pH. This problem can be corrected with a neutralizing calcite filter, a water softener, raising the pH to a

minimum of 6.7, or oxidation with chlorine bleach followed by filtration. Manganese can be removed from water by reverse osmosis and by oxidation with chlorine bleach followed by filtration. Small concentrations of manganese can be removed with a water softener. Hydrogen sulfide in concentrations greater than 6 ppm is treated with constant chlorination followed by filtration/dechlorination (Spoljaric 1994).

Absorbents

Substitute materials for absorbent minerals include such organic materials as paper, sawdust, ground alfalfa, corn cobs, and citrus fruit grinds. Their major advantage over specialty clays is little or no dust with these not-in-kind products. But, although these materials are typically less expensive, they are not as effective as specialty clays. On the other hand, such synthetic materials as molecular sieves, silica gel, precipitated silica, and nonwoven polyethylene fabrics are very effective but are too expensive. In more limited cases, such mineral products as vermiculite, gypsum, lime, sand, and zeolites are used in specific applications where low cost or performance is desired. Other substitutes include diatomite and perlite, especially in the western United States, because of the transportation cost advantage that they have over clays (Harris and Eckert 1989). Waste fiber products from International Absorbents look and feel like clay, are healthier than clay, and are flushable and price competitive. The agriculture granular market is stagnant for the clays because new biotechnology products have taken some market share and because of U. S. Environmental Protection Agency (EPA) cancellation action against some granular clay products.

Polyethylene fabric has had the largest impact on the demand for mineral absorbents. These nonwoven fabrics have a natural affinity for petroleum-based products, and so they can absorb up to 20 times their weight of oil and grease. The use of these materials has grown because of the classification of spent clay as a hazardous material and the subsequent disposal costs associated with these clays. The big advantage of these nonwoven fabrics is that they can be incinerated with less than 1% ash remaining (Harris and Eckert 1989).

Rheology Modifiers

Minerals used as rheology modifiers receive competition from naturally occurring or synthetic polymeric additives.

Proppants

The demand for high-quality proppants at depths exceeding those that can be adequately served by sand has resulted in sand being increasingly replaced by ceramic proppants based on mixtures of kaolin and bauxite or bauxite alone.

ENVIRONMENTAL AND HEALTH REGULATIONS

Governmental regulations concerning crystalline silica have had an adverse effect on the demand for diatomite. This trend began in 1988 when the International Agency for Research on Cancer (IARC) classified crystalline silica as a probable carcinogen. The classification triggered regulation of crystalline silica at a threshold concentration of 0.1% in materials under the Occupational Health and Safety Administration's Hazard Communication Standard (Miles 1990).

Diatomite and other minerals suppliers responded to this in a number of different ways, including worker and user training programs, product labeling, and dust reduction programs. The diatomite industry also created the International Diatomite Producers Association (IDPA) to study and issue reports on health, safety, and environmental issues related to the use of diatomite. Other mineral and

chemical producers formed a Chemstar Crystal Line Silica Panel. This panel, formed in 1989 and sponsored by the Chemical Manufacturers Association (CMA), works with government agencies to avoid random banning of minerals suspected of being hazardous.

Another governmental regulation that has reduced demand for minerals and rocks used as filters and absorbents was the 1991 EPA ban on disposing of wastes containing oil in landfills. This ruling caused some consumers of clays for oil and grease absorbents to switch to other products. The switch was mainly because organic products could be incinerated instead of being placed in landfills. Clay suppliers are currently fighting to have new tests approved for measuring the leaching or leaking of absorbed oil from clay products. Under the current regulations, a toxicity test renders the clays hazardous, but if proposed liquid release tests are accepted, the absorbent minerals may prove to be less hazardous.

The area of southern New Jersey where glauconitic greensand is being produced is heavily populated. It is likely, therefore, that any new mining permits or changes to current land use zoning to accommodate expansion of the greensand mines will be difficult to obtain. In 1988, however, Inversand Co. had reserves estimated to be sufficient for at least 20 to 25 years of production.

Inversand Co. is required to comply with a number of environmental regulations and to operate a wastewater treatment plant under the jurisdiction of the New Jersey Department of Environmental Protection (New Jersey Pollutant Discharge Elimination System, or NJPDS). The company must have permits for both surface water discharge and groundwater discharge. Its operations are inspected periodically by the Mine Safety and Health Administration (MSHA), which checks workers for exposure to crystalline silica dust and enforces regulations regarding safety practices.

PROBLEMS AND FUTURE TRENDS

Although health and environmental regulations will continue to lessen demand for industrial minerals and rocks, they will not cause the demise of the use of these materials. Overall, the minerals and rocks used as filters and absorbents do their job very effectively and economically. The regulations may increase the cost, but in most cases the increased cost will not immediately result in the substitution of alternative materials or technology. Therefore, despite the regulations, the use of minerals and rocks as filters and absorbents will continue to be cost-effective.

Market Developments

Environmental issues will continue to affect the demand for industrial minerals and rocks. In many areas of the United States, the closure of landfills has been increasing the total cost to dump material. The total cost includes fees for material disposal and the added cost to transport the material to a more distant landfill. In addition, landfill users can incur additional liability if a site requires future cleanup because of another user's disposal practices (Miles 1990).

The EPA ruling that spent clay oil and grease absorbents are classified as hazardous wastes also will continue to reduce the demand in this application. Another area that has caused problems in the past is the disposal of spent clays from edible oil filtration. The problem is that the spent clay product is highly flammable and special precautions must be taken when dumping the material. Although procedures have been developed to safely dispose of used material, some landfills still do not accept such material (Harris and Eckert 1989).

The end result of increasing disposal costs for spent filter cake and clay absorbents will be increased substitution or new technology to circumvent these problems. For example, diatomite and perlite will continue to lose market share to ultrafiltration or membrane

technology. Another example of consumers switching to a different technology because of increasing spent clay disposal cost is in the petroleum refining industry. Refineries are increasing their hydrogenation capabilities, which is another way of cleaning or purifying petroleum products without incurring the additional cost and liability associated with disposing the spent clay (Harris and Eckert 1991).

The crystalline silica issue will continue to be a problem for the industry. The initial negative impact of the regulation appears to have peaked in 1991. Consumers have either taken protective actions and continued to use diatomite or they have switched to another material. The 0.1% target, however, may not be final and could actually be changed. If it is lowered, more problems await both suppliers and users of any mineral product containing crystalline silica.

On the other hand, increased environmental regulations will also have a positive impact on the demand for these materials. Because of more stringent regulations on wastewater, companies will be required to clean their effluents, and filtration will be one of the methods.

Specialty clays used as pet litter is another area that will show good growth. The cat population in the United States is expected to continue to increase as the population ages. Cats are, in many ways, ideal companions, especially for the elderly and apartment dwellers, because they care for themselves, require no outdoor exercise, and consume little food.

In light of declining demand for greensand, efforts have been made recently to develop new uses. Glauconite's catalytic properties have been investigated in some detail in the United States, the former U.S.S.R., Japan, Germany, and France (Hartough and Kosak 1947; Kvirikashvili 1962, 1964). Acylating reactions, dehydration of cyclohexane to benzene, and condensation of aldehydes have been carried out with glauconite-based catalysts. The relationship between catalytic activity and cation-exchange capacity (CEC) has encouraged efforts to enhance the former by increasing the latter through heat treatment and chemical methods. Because CEC increases with the amount of mixed-layer component present, these efforts also have focused on replacing more of the potassium in the glauconite structure with hydroxyl ions. Heating of glauconite in a reducing atmosphere leads to the formation of metaglauconite, the sorptive properties of which are being studied.

An entirely different approach is the destructive dissolution of glauconite and recovery of at least three marketable products: high-purity silica, potash, and iron oxides. This process was first proposed in the mid-1920s. Efforts are under way to prove its economic feasibility with the help of up-to-date chemical engineering practices.

Some extensive greensand deposits are situated near population centers. As a result, glauconite's capacity to absorb hazardous waste fluids is being investigated, and an increasing demand for this mineral in solving pressing pollution problems can therefore be anticipated. Food shortages in several parts of the world may also bring about renewed interest in glauconite as an inexpensive fertilizer.

Outlook

The outlook for filtration and absorbent materials will vary considerably by end use. For the most part, however, many of the markets are mature and the growth is expected to follow the overall economy. Average annual growth of filtration and absorbent materials in the 2000s will range from mostly flat to 2% a year (T. Harris, personal communication). Most end use applications for diatomite are mature with relatively static projections for future growth. Although

pet litter demand tends to grow with the population, the loss of markets to substitute materials and alternate technologies because of environmental and health problems could worsen and thus lower the average annual growth rate. Consumption of organoclays in consumer and industrial markets is forecast to grow at a compounded annual growth rate of less than 1% a year. This low rate is almost entirely caused by flat sales to the paint sector (T. Harris, personal communication).

ACKNOWLEDGMENTS

The authors would like to thank John Wolford (specialty clays) and Christina Prowell (propagants) of Engelhard Corp. for providing updated information. Fine Ceramic Products

Denis A. Brosnan and John P. Sanders

INTRODUCTION

Fine ceramics such as ceramic dishes, toilets, tile, and related products (Figure 1 A–D) are part of our everyday lives. Clay minerals are used in the composition of all these products, which are processed at high temperatures to cause limited melting or fusion. This produces a glass or vitrified phase that creates a permanent bond within the articles and gives them their permanence and utility.

Ceramic products are composed of nonmetallic and inorganic constituents. In other words, ceramics are composed of oxides, and traditional ceramics have constituents that commonly occur in the earth's crust. This means that traditional ceramics contain oxides of aluminum, silicon, magnesium, calcium, iron, and alkali metals (sodium and potassium), along with trace quantities of other elements.

Fine ceramics are essentially made from fine particles, with particle sizes less than about 150 μm and typically less than 75 μm . After heating (also known as firing), such ceramics have a fine texture—meaning that the solid material consists of crystals and amorphous phases with dispersed areas of pores of small diameter.

By contrast, some traditional ceramics are made from large or coarse particles ranging in size up to about 6,000 μm . These include products such as clay bricks, clay roofing tile, refractory bricks, and clay pipe. Although coarse particulate ceramics are fired in kilns or furnaces to achieve permanence, they generally exhibit lower strength than fine ceramic products. Another important distinction is that many coarse particulate ceramics may contain iron oxide in their composition in the range of 2% to 8% by weight, producing colors in the fired products ranging from pink to red to blue (or black).

Technologists apply the name *whitewares* to fine ceramic products, and the term simply reflects the fact that most of the products are white (or near white) in color. *Ware* is the technical name for a ceramic object that is sold in commerce. Whitewares include many different classes of functional products (Table 1). Whitewares are distinguished or classified in commerce according to technical subgroups based on use. The classifications are also correlated with the amount of void space in the fired ceramic, which is called its porosity. In the historical development of traditional ceramics, porosity was measured indirectly as water absorption (i.e., the weight of water the ceramic would absorb on immersion compared to the dry weight of the ceramic object), expressed as a percentage of the dry weight.

The general relationship in whitewares is that low porosity is associated with high mechanical strength, high resistance to chipping (or breakage), and excellent durability. Adjusting the composition or mineral constitution and increasing the amount or degree of vitrification in firing are means to achieve low porosity in whiteware manufacturing.

With respect to composition, mixtures of clay, flint (ground silica), and feldspar minerals achieve high strengths in clay-based whitewares. These products are called *triaxial* whitewares because of the three components in their composition. Further improvements in strength are obtained when aluminum oxide (alumina) or other minerals such as zircon are added to the composition.

Vitrification is achieved in kilns as the ceramic composition melts when temperatures achieve red heat (i.e., rise above about 950°C). As temperature increases further in the kiln, more melted phase is formed, and this glass is distributed by capillary forces throughout the ceramic. When temperatures increase above 1,000°C, a new mineral, mullite, appears. Simultaneously, the ceramic ware shrinks, effectively increasing density and reducing porosity. Residual pores tend to “grow” or increase in size during the highest temperature period of firing. After cooling in the kiln, the fired product has mechanical properties that reflect the degree of vitrification and densification achieved in the firing process.

The degree of vitrification is the percentage of melting of the original constituents that has occurred in manufacturing. In whiteware ceramics, the amount of melting may exceed 40% to 60%. In glass products, the extent of melted phase approaches 100%. In manufacturing of white wares, measurements of firing shrinkage and porosity (water absorption) reflect the extent of vitrification during firing (i.e., the quality of the fired product).

Whiteware products may be glazed to increase their utility and improve their appearance. A *glaze* is a glass coating formed by melting or fusing an applied particulate mass over all or part of the ceramic ware's surface. Glazes provide a smooth surface that can easily be cleaned, and they also prevent water from being absorbed by the product, promoting sanitation and improving performance. Glazes can also be colored using pigments or oxides, which enhance the appearance of the finished product.

One advantage of glazing over a white surface is that it is relatively easy to achieve light colors without color bleeding through from the substrate ceramic. This is a distinct advantage of whiteware products over red clay (red body) ceramics. With red clay

Figure 1. (A) Fine china cup and saucer (Lenox, United States); (B) cup with unique black porcelain saucer (Rosenthal, Germany); (C) toilet in a bathroom with porcelain wall and floor tile; and (D) kitchen application of tile products

ceramics, it is frequently necessary to apply double layers of glaze (a white underglazed, or engobe layer covered by a colored outer layer) to achieve a desired light color.

RAW MATERIALS AND REACTIONS ON FIRING

General Information

A variety of raw materials are used in the production of whiteware ceramics. These raw materials or minerals can be broken down into three categories: clay (kaolin and ball clay), flux, and fillers (or nonplastics). Each material has a specific function, but in general, the clay is the component that provides plasticity or cohesion for forming and the flux promotes vitrification. The filler is inert, but it also may serve to modify the glass viscosity during vitrification, which effectively extends the usable range of firing temperatures for the composition.

Clay, which is composed of kaolinite, is a hydrous sheet silicate produced by the weathering of feldspathic rock, is the component of primary importance in traditional ceramic compositions. Characterized by plasticity when mixed with water, clays exhibit an extremely small particle size in an unagglomerated state. Figure 2 gives a typical particle-size distribution. The small particle size and the plate-like morphology of the particles result in a large surface area. The particle surfaces, then, tend to have an affinity for water. The clay's affinity for water gives rise to a monolayer of water around the particle. The water layer promotes cohesion and allows the particles to slip relative to one another during forming.

Because kaolins are the product of weathering of the parent feldspathic rock, they can exist as either primary (residual) deposits or secondary (sedimentary) deposits. Primary deposits are formed by geological processes in situ, and they typically have the coarsest particle size and highest impurity level among clay sources. Secondary deposits of clay involved transportation of minerals by

water, with eventual deposition in the location where they are now mined. Secondary deposits typically exhibit smaller particle sizes and lower impurity levels when compared to primary deposits.

As a product of weathering, clays are capable of a wide range of atomic substitution in the silicate structure, which gives rise to the large variety of clay minerals. Clays also contain nonclay impurities or accessory minerals.

The major accessory mineral found with clay deposits is crystalline silica (quartz). Sulfides, sulfates, carbonates, and hydroxides can also be present. Clays also contain organic impurities. The organic impurity can play a role in the plasticity of the body, and it can be a rate-limiting factor in fast-firing applications, because carbon must be removed by oxidation in firing. A variety of processing and refining steps can remove impurities before the clay is incorporated in whiteware compositions, but the cost of these treatments may be prohibitive. Clays are available in lump or prill, powdered (air-floated), and slurry forms.

There are three main groups of clay minerals used in whitewares—kaolin, illite, and smectite. Kaolin clays are the most common group, and they have the approximate composition of $\text{Al}_2(\text{Si}_2\text{O}_5)(\text{OH})_4$. White clays of this type are composed of the clay mineral kaolinite. Kaolinite is also the major clay mineral in ball clay—a highly plastic and cohesive sedimentary clay. Depending on the origin or geologic history, kaolins are used in several forming processes (product shaping), ranging from pressing for kaolins from Georgia (secondary kaolins with extremely small particle sizes) to casting for the coarser kaolins.

Kaolin

Table 2 gives selected chemical analyses of kaolins. Because fired color is a concern with kaolins, the iron content (reported as Fe_2O_3) and titanium (reported as TiO_2) content are very important. As the iron content increases, the fired color develops a red shade. Increasing titanium content imparts a buff or tan color. For products where extreme whiteness is desired, clay with a minimum level of these impurities must be selected.

Kaolinite undergoes chemical reactions during firing. The first and most important reaction is dehydroxylation. During this reaction, the crystalline water (or hydroxyl units) is evolved from the clay mineral above 500°C . Evidence of dehydroxylation is given in Figure 3, which is a simultaneous thermogravimetric (TG) and differential scanning calorimetry (DSC) analysis with evolved gas analysis of a commercial kaolin. After dehydroxylation, the clay mineral is in a disordered form that exists as a residual material called metakaolin.

A second reaction, at about $1,000^\circ\text{C}$, is apparent in Figure 3, and it is associated with mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) formation. This reaction is characterized by a large exothermic peak indicating the reaction. During the reaction, a portion of the clay mineral reorganizes or recrystallizes to form mullite. Mullite formed during the initial heating is called primary mullite. Mullite is considered advantageous because it has a needlelike crystal habit, and it mechanically reinforces the glassy matrix of the whiteware ceramic.

On heating above about 950°C , some of the residual material from the clay dehydroxylation forms amorphous material as melted phase or glass. Impurities and other minerals contribute to the overall quantity of vitrified material during firing. On cooling, additional mullite (called secondary mullite) can crystallize from the glass present. The process of forming secondary mullite involves expansion reactions, and it may help prevent excessive shrinkage or slumpage of the ware at the elevated temperatures in the kiln.

Table 1. Classification of unglazed ceramic whiteware products

Class	Description	Distinguishing Factor for this Class
Earthenware	Clay-based ceramic ware of medium porosity.	Water absorption of 4%–20%. Earthenware is typically off-white to red because of its iron content.
Stoneware	Ceramics made from a single clay or clay blend with other minerals (including silica) fired to produce harder and more durable products.	Water absorption of 0%–5%. Stoneware is typically off-white to gray because of its iron content and the presence of nonclay minerals.
Vitreous china	Very low porosity and highly vitrified products. Product classes include: Hotel china Bone china Frit china Vitreous plumbing fixtures Cookware	All product classes typically exhibit water absorption of less than 0.5% except for cookware, which may exhibit up to 5% absorption. The low water absorption creates high strength and negligible water transmission in use.
Porcelain	The lowest porosity and highest strength of traditional ceramic products. Product classes include: Hard porcelain Vitreous porcelain Electrical porcelain Dental porcelain	The products may be compositions of flint (quartz), clay, and feldspar (vitrification enhancer), and they may contain additional minerals to increase their strength (such as aluminum oxide).
Electrical porcelain	Compositions are adjusted depending on the intended application. Product classes include: Steatite ceramics Electrical ceramics	Steatite ceramics contain the mineral talc to enhance the product performance in high-frequency electrical applications. Electrical ceramics are usually porcelains of high aluminum oxide content (such as spark plug insulators).
Technical whiteware ceramics	This general classification includes many low-absorption ceramics for structural and chemical applications.	Compositions are altered to include aluminum oxide, zircon, and other minerals to obtain specific properties.

Ball Clays and Other Clay Minerals

In addition to kaolin, there are other commercially important clay minerals. Ball clays are commonly used in whitewares where higher plasticity is required. Ball clays typically fire to buff or tan because of their iron or titanium dioxide content. Table 3 gives selected ball clay chemistries.

Smectite is another class of clay minerals. Often referred to as *montmorillonites* $[(Al,Mg)Si_4O_{10}(OH)_2]$, smectites are characterized by small particle size and a very high level of plasticity. As the chemical formula implies, montmorillonites are subject to a high degree of atomic substitution. Montmorillonite, in the form of bentonite, is used in limited quantities to improve plasticity in whiteware compositions. Their fine particle sizes cause montmorillonites to produce high drying shrinkage, and their presence can make drying more difficult. They fire to darker colors than kaolins or ball clays because of their impurity levels.

Another clay mineral used in whitewares is illite, which is sometimes known as *hydrous mica*. Illites have a variable composition because of the wide variety of atomic substitutions that can take place. Illites are desirable for fast-fired tile formulations because they exhibit lower weight loss and shrinkage on firing than most other clay minerals. Table 3 gives examples of illite and montmorillonite chemistries.

Fluxes Used in Whitewares

Fluxes promote the formation of a glassy bond during vitrification. Fluxes provide alkali (Na_2O and K_2O) or alkaline earth (CaO or MgO) elements to the composition, promoting glass formation and reducing glass viscosity during firing. This serves to enhance vitrification. The level of fluxing components must be optimized to achieve the desired fired property in the selected firing range. Feldspars and nepheline syenite are the usual fluxes, but recycled glass powders and other waste materials are gaining popularity for cost reasons. Materials such as spodumene $[(Li,Al)SiO_3]$, calcined bone ash $[(Ca(PO_4)_2]$, limestone ($CaCO_3$), dolomitic limestone

[(Ca,Mg)CO₃], wollastonite (CaSiO₃), and talc [Mg₃Si₄O₁₀(OH)₂] are also used as fluxes.

Several types of feldspar are used in white wares, including soda feldspar (albite, NaAlSi₃O₈), potash feldspar (microcline or orthoclase, KAlSi₃O₈), and lime feldspar (anorthite, CaAl₂Si₂O₈). Feldspar does not exist as pure albite or pure anorthite, but it is found as mixtures of these major types. It is possible to buy a soda feldspar, for example, but this simply means that albite is the predominant mineral. Particle sizes can range from granular to powders, and the selection of particle size depends on the application. Feldspar usually contains quartz as an impurity. Table 4 gives some examples of feldspar chemistries.

Another flux used in white wares is nepheline syenite, a material that is higher in alkali and alumina and lower in silica than feldspar. Nepheline syenite is a naturally occurring mixture of nepheline (K₂Na₆Al₈Si₉O₃₄) with microcline and albite feldspars. It is relatively expensive, but it provides greater fluxing power (effectiveness) and a wider firing range than feldspars in porcelain compositions. Additionally, it does not usually have significant quartz contamination, although it may contain a trace of mica.

Fillers for Whitewares

The nonplastic or filler portion of the whiteware composition consists of flint (ground quartz), and it may include alumina (Al₂O₃), pyrophyllite [Al₂Si₄O₁₀(OH)₂], or sericite depending on desired function of the filler. Ground quartz used in whiteware compositions is frequently called *potter's flint*.

In the case of quartz, the silica particles are partially melted at high temperatures (above red heat) and enter the glassy phase formed by the fluxing components. One result is the increase of the viscosity of the glassy phase, thereby allowing for a relatively wide

Figure 4. Quartz inversion by DSC

firing range characteristic of porcelain compositions. The residual or unmelted quartz serves as a "skeleton," which prevents the product from slumping under its own weight at elevated temperatures.

Quartz undergoes a reversible phase change during firing, requiring special care during cooling of the fired ware in the kiln. On heating, quartz inverts from the α quartz polymorph to the β quartz polymorph at 573°C with an accompanying expansion. The reverse reaction takes place on cooling for any residual quartz grains. Figure 4 shows an example, illustrating the heat associated with the quartz inversion on heating and cooling.

On heating, the phase change consumes heat (is endothermic), but on cooling, the reaction releases heat (is exothermic). A potential problem arises from the 2% volume expansion on heating and an equal contraction on cooling. Excessive cooling rates in the kiln can result in a defect known as *dunting* (cracking), where the volume contraction during the quartz inversion is the cause of crack formation and extension.

When alumina is added to a whiteware composition, increased mullite formation increases the strength of the fired ceramic. Alumina porcelains are commonly used when very high strength is required. When alumina is substituted for quartz as the filler, *dunting* becomes less of a concern, compared to compositions containing a high content of flint.

In steatite compositions, talc is used as a source of magnesium. Talc is also used in the production of cordierite ceramics, which have a very low thermal expansion and are used as substrates in catalytic reactor products.

Glazes

Raw materials used for glazes include clay, finely ground silica, and fluxes. High alkali and alkaline earth contents and low silica contents are desired in glazes to achieve good flow (coverage)

during firing. Changing the alumina content, for example, makes glazes with a gloss finish exhibit a matte finish instead. In some cases, lithium silicates (such as spodumene) are added to glazes to modify their thermal expansion characteristics to achieve better thermal expansion match (equivalence or fit) between the glaze and the ceramic body.

Because the use of lead as a flux has been curtailed, borates and zinc oxide are employed in small quantities as fluxes. Zinc oxide also promotes color development in the fired glaze. A common source of borates is borax (sodium tetraborate decahydrate). The levels of both zinc oxide and borates must be limited to avoid glaze defects.

Glazes are now commonly prepared from frits (premelted glass compositions). Frits have the advantage of requiring low energy to melt, and they involve less batching and material handling effort. Frits simply require milling and mixing with the remaining glaze components to prepare the glaze suspension prior to application. Frits are used to achieve a particular effect for which they were specifically prepared.

Clays are used in glazes as suspending agents in preparing the glaze slurry. It is possible to purchase premixed combinations of frit and clay (known as *compostos*). These formulations simply require a water admixture to form a suspension, and coloring agents are added to achieve visual effects.

Transition metal oxides such as hematite (Fe_2O_3) or cobalt oxide (CoO) can be added directly to formulations to impart color. These oxides are dissolved by the glassy phase during firing. Recently, ceramic pigments based on zircon have become popular because of their stability and coloring power in glaze formulation. These colorants are zirconium silicate crystals with additions of transition metal oxides to achieve a coloring effect. Pink colors are based on chemically *doped* alumina.

Zircon (ZrSiO_4) is used as an opacifier for white glazes and engobes (thick coatings). On cooling of the molten glaze, the zircon that has been dissolved in the melt precipitates and forms discrete crystals in the glassy matrix. These crystals block the transmission of light and scatter light entering the glaze, effectively masking the substrate.

FORMING METHODS FOR WHITEWARE PRODUCTS

Whiteware products are shaped (formed) by the conventional processes of plastic forming (turning, jiggering, extrusion, or combinations thereof); slip casting; or compaction (wet or dry pressing). In a few products, dry isostatic compaction may be followed by turning in lathe-like machines to achieve a formed shape. Drying, firing, and quality inspection follow these processes. Glazes may be applied before firing (in single-fire processes) or after firing (in double-fire processes); the latter product is then fired a second time to melt the applied glaze to the surface.

The object of forming is to achieve near-perfect particle packing in the formed mass. This means that entrained air has been reduced to the extent practically possible. In addition, constituents of the mixture are uniformly dispersed in the mass before the forming process is used. The wetting of materials, as required by the forming process, is achieved in special mixers, and it is frequently aided by the “aging” of wetted raw material mixtures. There is considerable art and science in preparing raw materials for the forming process to achieve optimum properties in the formed ware.

Plastic Forming

As the name implies, plastic forming involves deformation of a plastic mass of raw materials into a desired shape before the product is dried and fired. By definition, plasticity (in ceramics) is the property allowing the mix to be deformed without breaking or cracking. Plas-

ticity originates from the clay constituent of the mix, and it may be increased through mineral additions and polymeric additives.

The simplest plastic forming process is hand forming, as is practiced by potters. In high-volume manufacturing, jigs are used to force the plastic mass into a consistent shape. In many cases, the plastic forming process forces the mass into a mold cavity under pressure, in a process called *plastic pressing*. If the mold is permeable, air may be used to assist in ejecting the formed product from the mold after pressing, in a process called *ram pressing*.

The most common plastic-forming process is extrusion, where the plastic mass is forced through an orifice (die), which forms two of the three dimensions of the desired product. Extrusion is carried out in piston-type or auger-type devices. In higher volume manufacturing, the auger extrusion device may be preferred because of high production output. The “column” of the composition is then cut with wires to form the third dimension of the formed product. Some products, such as electrical insulators, may be formed by extrusion into plastic “blanks,” and the blank is subsequently pressed or turned in lathe-like processes to accomplish additional forming of surface features. To avoid slumpage of the wet clay mass after forming, some degree of drying may be required between extrusion and the subsequent turning operation.

Formed ware is always purposefully greater in dimension than the fired product because of shrinkage in drying and shrinkage in firing. The drying and firing shrinkage can exceed 5% to 8% linear shrinkage in plastic formed products. For this reason, the formed dimension is always adjusted so that the net dimension after firing is the required product size.

Slip Casting

In slip casting, a suspension of ceramic particles is poured (cast) into a permeable or absorptive mold to draw a layer of particles to the surface of the mold, forming the product. Slip casting can be used to make both solid and hollow objects. Drain casting is the process of timing the casting process until the desired wall thickness of cast product has formed, and then draining the mold, preserving a void or cavity in the cast object.

After the casting process or draining is completed, the cast object is left in the mold until the mass has been dewatered sufficiently to allow handling of the formed object without deforming it. Then, the mold is opened and the cast object is withdrawn. The object is placed on a tray or other fixture and conveyed into a conditioning room before drying.

The slip casting process is preceded by the production of a batch of the required proportions of minerals. This batch is mixed with water and chemicals in special mixers called *blungers*. The mixed material is stored in tanks that are agitated to prevent settling of the constituents of the suspension. The suspension is typically called the *slurry*.

The slurry contains chemicals that cause deflocculation or separation of the fine mix constituents. Some chemicals assist in wetting of the particulate matter and stabilization of the slurries. The solids content of the slurry is carefully controlled by meeting goals for the specific gravity of the slurry, and the viscosity of the slurry is monitored. Controlling the solids content of the slurry and its viscosity keeps the casting rate (rate of buildup of solid on the mold surface) consistent, allowing the use of discrete schedules for draining molds.

The usual mold material in slip casting is plaster of paris. Such molds must be handled carefully to avoid breakage or wear, and consistent mold moisture content before reuse is important. Polymer molds have been introduced in pressure casting operations where applied pressure over the mold increases the casting rate.

Dry Pressing or Dust Pressing

Powdered mineral mixtures can be formed by compaction in molds using large presses. The process is called *dry pressing* or *dust pressing*, and it is used extensively in producing ceramic tile and certain electrical ceramics. The process begins with the preparation of the powdered material using a granulation process. Granulation is required so that the dry or near-dry powders will flow into mold cavities, achieving even fill before compaction. In high-volume manufacturing, spray drying is used to form granules 1 mm or less in diameter, and these granules, or pellets, are stored before use in pressing. In lower volume manufacturing, mix-pelletizing may be used to produce granules. Granules can have a small percentage addition of moisture, binders, or plasticizers added before their use in the pressing operation.

Modern presses employ isostatic molds that allow for even pressure application to the surfaces of the part during compaction. The rate of compaction is important to allow de-airing during the press cycle, and the total pressure applied in compaction largely determines the as-pressed or “green” strength of the pressed ware.

DRYING AND FIRING OF WHITEWARES

Drying

Drying is conducted in continuous convection dryers containing zones to control evaporation rate. The initial drying may be accomplished in predryers in which the rate of evaporation is held as low (using low temperature and high relative humidity) as needed to avoid high shrinkage rates and associated cracking. In the first dryer zone, temperatures are kept just below the boiling point of water to avoid steam spallation in the product. In the final dryer zone, the temperature can reach 150° to 200°C.

Radio frequency and microwave dryers speed up the processing of high-valued whiteware ceramics. Such dryers allow for greatly reduced drying time, and they are amenable to larger objects like electrical insulators. Convection dryers remain popular because most ceramic plants have excess waste heat available from the cooling section of their kilns.

Firing

Firing ceramics involves heating the dried ceramic to high temperature at a defined heating rate, holding (soaking) for a discrete time, and cooling back to room temperature under a defined cooling schedule. Firing is accomplished in batch kilns or continuous kilns. Batch kilns hold a defined quantity of product and go through a complete firing schedule before unloading of the fired product. In continuous kilns, the product is continuously charged to one end of the kiln, and it moves through the kiln at a uniform rate before discharge. Continuous kilns include tunnel kilns (where the product is set on kiln cars) and roller hearth kilns (where the product sits on and is propelled by ceramic rollers).

PHYSICAL PROPERTIES OF WHITEWARES

Key Physical Properties

The product requirements determine the physical properties of fired whiteware ceramics, and the properties can vary widely depending on the specific formulation, additives, forming method, and firing. Table 5 lists key physical properties by product.

Water adsorption, or porosity, is a critical physical property for all types of whiteware ceramics. Low values of porosity indicate a high degree of vitrification. Some product standards specify that a product must be impervious, which is defined as exhibiting a water adsorption of less than 0.5%. Many products are glazed on any surface that will be exposed to water during use to improve their resistance to water adsorption.

Methods for determining water adsorption and porosity for whiteware ceramics are described in ASTM C373 or in ISO 10545-3. In these methods, the ware is exposed to saturation for a specific period of time to determine the quantity of water that the ware can adsorb. Saturation can be achieved through boiling or vacuum, depending on the method.

Mechanical Properties

The mechanical strength of a whiteware product is important for many types of applications. For sanitary ware, the product must be able to resist the stresses applied during normal use; for tile, the product must be able to withstand the compressive load applied to the floor. Strength tests can be used to measure compressive strength or tensile strength, depending on the application. The most common type of test for the mechanical strength of whitewares is a simple bending or flexure test. Bending tests such as a modulus of rupture test measure the tensile strength of the ceramic in flexure. As with all ceramics, whitewares tend to fail more readily under a tensile stress than under a compressive stress because of their brittle nature.

The flexure test method is given in ASTM C648, ASTM C674 or ISO 10545-4. In these tests, a load is applied that flexes the ware, and this load is applied until failure occurs. For many intricately shaped products such as toilets or other sanitary ware, it is difficult to measure strength on the finished product because of the irregular geometry. For these products, samples can be cut to measure mechanical properties. Table 6 gives typical mechanical properties of whiteware products.

Another aspect of mechanical strength is impact resistance. For tableware, the product must have sufficient impact resistance to withstand dropped utensils or to resist impact stress in handling. Impact resistance not only is a function of the mechanical properties of the fired ware but also has to do with the physical design of the product. ASTM C368 gives methods for measuring impact resistance for tableware. A pendulum arrangement can determine the magnitude of impact that will initiate failure and the amount of energy required to produce complete failure. A similar method, described in ISO 10545-5, exists for ceramic tile.

For products subjected to wear in flooring applications, resistance to abrasion is a key concern. For glazed ceramics, the abrasion resistance test measures the resistance of the glaze and not that of the underlying ceramic ware. Tableware must be able to resist degradation by abrasive cleaning agents.

ASTM C1027 and ISO 10545-7 describe the measurement of abrasion resistance of ceramic tile. In these methods, an abrasive load is agitated on the glazed surface of the tile for a set number of cycles. The surface is inspected at specific intervals. Observers note the number of cycles that the product passes through before the surface is degraded and that observation determines the category of abrasion resistance.

For unglazed surfaces, the procedure for measuring abrasion resistance is slightly different. In these methods, a large wheel is rotated over the ceramic surface. The wheel can be made of abrasive material or abrasive grit can be introduced to the rotating wheel just above the surface of the ceramic. The loss of mass after a defined number of rotations is used to determine the abrasion resistance. ASTM C1243 and ISO 10545-6 give examples of this type of measurement.

Chemical Resistance

Chemical resistance is especially important for products that are in contact with food or exposed to harsh cleaning agents. Staining resistance is important for similar reasons. Properly formulated and

* na = not available.

fired glaze compositions should be very resistant to household chemical attacks and easy to clean. Some unglazed surfaces such as mechanically polished porcelain tile can exhibit poor staining resistance because closed pores near the surface can be exposed by the polishing process.

Most chemical and staining resistance tests involve exposure to the chemical or staining agent followed by a specified cleaning procedure. After the cleaning procedure, the surface is inspected under specified viewing conditions, and the results are qualitatively determined. Staining resistance indicates how easy the surface will be to clean after use. ASTM C650 and ISO 10545-13 give examples of methods for measuring chemical resistance, and ASTM C1378 and ISO 10545-14 give examples of staining resistance methods.

The resistance of tableware to “metal marking” is related to staining resistance. In this case, the glaze must resist staining when cutlery is passed across the surface. Resistance to metal marking is a function of both the condition of the glaze surface and the composition of the glaze. Typically, glossy surfaces are more resistant than matte surfaces.

The leaching of metals from tableware is also related to chemical resistance. Test methods have been developed specifically for cadmium and lead release from ceramic products. One concern is that acidic components of food or beverages may leach small quantities of these species from the glaze. Test methods such as ASTM C738 detail an accelerated leaching test for glazed ceramic surfaces that can be used to determine the potential risk of metal exposure from a particular glazed surface. The leaching takes place in an acetic acid medium, and atomic adsorption spectroscopy measures the quantity of metal leached from the surface.

Thermal Shock

Resistance to thermal shock is important for products such as sanitary ware, which may be subjected to rapid switching between cold and hot water. ASTM C484 reports a method for measuring thermal shock resistance. In this method, the ware is soaked in water at 16°C and then immediately moved to an oven operated at 145°C for up to 10 cycles.

**Figure 5. Thermal expansion of fired whiteware body and glaze**

Thermal Expansion

In most cases, it is desirable to measure the thermal expansion of the ware. This is often done in product development to match the thermal expansion of the glaze and the body. The coefficient of thermal expansion (CTE) is measured according to the following equation:

$$CTE = \frac{\left(\frac{L_2 - L_1}{L_1} \right)}{T_2 - T_1}$$

where L_1 is the length at temperature T_1 , and L_2 is the length at temperature T_2 . Thermal expansion can be useful for architects or engineers determining where to place expansion joints in large ceramic tile installations. The dimensions of the CTE are in./in./°F or simply /°F (and similarly cm/cm/°C or /°C).

Thermal expansion is measured using a dilatometer, which employs a ceramic pushrod to follow the dimensional change of a sample as it is being heated. ASTM C372 gives test methods for measuring thermal expansion with a dilatometer, and Figure 5 shows an example measurement of the CTE on a glaze sample.

Color and Gloss

Color and gloss are routinely measured on whiteware products. The first step in measuring color is to quantitatively describe color. The phenomenon perceived as color derives from the interaction between visible light and matter. This interaction can include adsorption, reflection, refraction, diffraction, scattering, and fluorescence. Adding to this interaction is the fact that color perception is strongly influenced by the illumination source.

The science of describing color received a great deal of attention in the last century. Of the several color measurement systems, the most common is based on the International Commission on Illumination (CIE) $L^*a^*b^*$ color system. These measurements describe a three-dimensional color space where the L^* value describes the whiteness or lightness of the article, the a^* value describes a red to green axis, and the b^* value defines a yellow to blue axis.

Two types of instruments for measuring color are available. These instruments have a selection of standardized illumination sources and illumination angles. Colorimeters are the simplest color-measuring instruments, and they use a set of filters to approximate the color space measurements and relate them to the standard observer curves published by CIE. Spectrophotometers are more advanced color measurement tools that measure reflectance and transmission data versus wavelength in small steps to describe the color.

Several standards, such as ASTM C609 and ISO 10545-16, exist to quantify small color differences between glazed surfaces. The color difference, ΔE , is defined as the magnitude of the difference between the vectors describing the color of each sample, as is shown in the following equation:

$$\Delta E = \sqrt{(\Delta L)^2 + (\Delta a)^2 + (\Delta b)^2}$$

The measurement of gloss is related to color perception. One common method for quantifying the perception of gloss is the method for measuring specular gloss described in ASTM C584. In essence, high-gloss surfaces result in very little scattering of the incident light. More scattering occurs as the amount of surface texture increases. Opacity measurements can also be made on translucent glazed products.

Electrical Properties

ASTM D116 summarizes the method to determine the electrical properties of whiteware ceramics. This method describes measurement of dielectric strength, electrical resistivity, and other properties of ceramics intended for electrical insulating applications.

GLAZES FOR WHITEWARES

Glazes are thin glass coatings applied to the whiteware surface. Glazes can be decorative layers or they may serve a purpose such as making the surface impervious so that it resists water penetration and staining. Glazes can be used to increase the electrical resistance or the mechanical strength of a particular product. Glazes are generally applied as suspensions (slips) of ceramic particles in water, but dry applications of particles are available. Functionally, the glaze formulation must readily bond to the ceramic surface and provide even surface coverage during melting in the firing cycle. The glaze should also have a similar thermal expansion to the body to avoid defects on cooling in the kiln.

A variety of constituents are used in glaze formulations; these can include materials used in the body formulations (clay, feldspar, and silica), and other components such as coloring agents, zinc oxide, carbonates of barium and strontium, and borates are usually present.

Silica (SiO_2) is the primary constituent of the glass formulation; it provides the network structure of the glass. The silica is derived from quartz (flint), clay, feldspar, or any other silicates in the formulation. Borates are unique in that they serve as network formers and they typically decrease the melting temperature. Excessive levels of borates can result in durability problems with the glaze. Borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$) is the primary source of borates, but other minerals such as colemanite ($\text{Ca}_2\text{B}_6\text{O}_{11} \cdot 5\text{H}_2\text{O}$) are also available. The boron content of a glaze is generally reported on a chemical analysis as boric oxide (B_2O_3). Lead (as PbO) was an integral part of any glaze formulation in the past. Adding lead to the glaze allowed a lower firing temperature and improved glaze coverage in firing. Leaded glazes produce a superior fired finish, but, because of health concerns, manufacturers severely curtailed lead usage, using instead zinc oxide and borates in glaze formulations. Zinc oxide acts as a flux, and it enhances the effect of other fluxes.

The silicate structure is modified by alkalis and alkaline earth components, which act as fluxes (reduce the melting temperature). These components “disrupt” the silicate structure, reducing the viscosity of the melt. The more alkalis and alkaline earth elements in the glaze, the lower the melting point, but care must be taken because excessive levels of these elements can result in durability or devitrification problems.

Alkalis and alkaline earths are introduced into the glaze from silicates such as feldspar, but they can also be contributed by soda ash or other carbonates and hydroxides. Care must be taken when dealing with soluble carbonates or hydroxides because they alter the rheology of the glaze. Also, high levels of alkalis and alkaline earth components increase the thermal expansion of the glaze. As the thermal expansion of the glaze increases, the likelihood of defects in the fired product increases.

Oxides such as alumina (Al_2O_3) are known as “modifiers” and help improve the chemical durability of glasses. Alumina can also be added to glazes to produce matte or satin finishes. Similarly, when zirconia is added to glazes, usually in the form of zircon (ZrSiO_4), it acts as an opacifier by precipitating zirconia crystals. Opacifiers based on titanium oxide and tin oxide may be required in combination with certain pigments.

Glaze Application

Glazes are applied in liquid or paste form, requiring that the ceramic components be in aqueous suspension. Glazes can be milled to achieve the proper particle size or, if the components are fine enough, can be simply mixed with water in a high-intensity mixer to disperse the suspension.

Frits are commonly used in glaze formulations. Frits allow the use of soluble components such as B_2O_3 , which would be difficult to incorporate in raw mineral form. Frits offer an energy savings because they are premelted and require less batching when preparing the glaze application.

Glaze formulations that require particle size reduction are ball milled to create homogeneous suspensions. As with slips for spray drying, the residue, solids content, and viscosity are monitored during milling of glaze suspensions. The residue is simply the amount of material retained on a selected screen, usually 200 or 325 mesh, after a sample of the glaze has been washed over the screen. The higher the amount of material retained on the screen, the coarser the glaze. Specific gravity can be measured with a pycnometer, and viscosity can be measured with either Zahn or Ford cups, the latter of which measure the time required for a sample of the suspension to drain through a specific diameter orifice.

The specific gravity (or viscosity) can vary widely with glaze slurries used for spraying and with thick pastes used for screen

applications. Binders or suspending agents are commonly added to glazes to achieve desired effects. Organic binders such as carboxy methyl cellulose (CMC) are commonly used, or a lternately bentonite or hectorite clay minerals are added to thic ken the glaze and improve green strength. Suspending agents such as kao lin, bentonite, or colloidal silica can be used to prevent settling in the glaze before application.

The oldest method of glaze application is dipping the ware into a bath of the glaze composition. This leaves a uniform coating of the glaze on the surface of the ware and facilitates application to intricate shapes. Handling the glazed ware, especially large or heavy pieces, can be problematic. Brushing is another simple technique to achieve uniform coatings of glaze.

A modern glaze line is a collection of modular glazing equipment that is assembled to achieve particular effects. The simplest operation is the bell or waterfall. In this system, a continuous flow of glaze is allowed to flow across a curved metal surface. The glaze, as a continuous "waterfall," is applied as the ware passes under. This application method is chosen to apply uniform coatings of engobes or glazes on wall tile.

Spray booths are also used to apply uniform glaze coatings. For some very intricate shapes, the glaze may be sprayed on by atomizing the glaze in a moving air stream. The glaze adheres to the surface of the ware when the droplets impact the surface. This application requires a skilled operator to achieve a uniform coating.

Excess glaze from these systems is collected and recycled in the glaze system. Usually screening is used to remove contamination from the glaze. Brushes or fettling systems remove excess glaze from the edges of tile. In some systems, brushes partially remove the applied glaze after an application, to achieve a particular visual effect.

For many applications, uniform coatings are not desired. Either patterns or random effects may be desired. Spray guns are used to apply mists of glaze called *fumes*. The guns can be stationary or move as the product, usually a tile, passes underneath. Timers are also used to turn the gun on and off to achieve a random effect. Patterns are applied with silk screens. A paste or thickened glaze composition is placed on the back of the screen, and when a tile passes under the screen, a squeegee moves across the screen, pushing the glaze through the screen and thereby applying the pattern to the tile.

Modern systems producing highly decorated tile use banks of screens that can apply multiple patterns to a single tile. Other systems apply a particular pattern intermittently to give a randomized decoration to the tile. In addition to flat screens, roller systems are popular. These roller systems can be operated asynchronously, which randomizes the decoration.

When a granular texture is desired, dry glazes or crushed frits can be applied to the tile. In these systems, a liquid glaze is first applied to the surface of the ware, and the dry glaze is then distributed on the surface. The liquid glaze helps the granular glaze adhere to the surface. This application technique can be used to apply abrasive to the surface of the ware to improve the slip resistance of the fired surface.

Hand painting and decals are used to apply a final decoration. This is especially true for fine china, where a ceramic decal may be applied to the fired glaze followed by a final firing to bond the pigments in the decal to the glazed surface. Decals made from ceramic pigments are available from a variety of sources.

Firing of Glazed Ware

During the maturing of the glaze in the kiln, a number of processes take place, including decompositions, solid-state reactions, vitrification, fusion, and crystallization. Although these processes tend to

Figure 6. Backscatter scanning electron microscopy (SEM) image of gas bubbles in a sanitary ware glaze

take place in the order listed, in fast firing this may not be the case. For example, decompositions may still be taking place as a glassy phase is developing, in effect retarding the rate of decompositions. Decompositions include the oxidation of organic binders, dehydroxylation of clays used as suspending agents, and decomposition of hydroxides, carbonates, or sulfates. These decompositions yield porous, high-surface-area components that react readily with other glaze constituents.

Before the formation of a glassy phase, some solid constituents react to form new compounds. These can generally be characterized as acid/base reactions. The acidic species is silica and the basic species are either alkalis or alkaline earth constituents. New compounds such as CaSiO_3 can be formed from CaO and SiO_2 at relatively low temperatures. The extent of the formation of new compounds is limited by the low mobility (low diffusion rate) of oxides in the solid state.

During vitrification, a glassy phase forms. The formation of this phase is a kinetic process, meaning that both temperature and time are important variables. This temperature/time relationship is called *heat work*. As the heat work increases, the quantity of glassy phase increases. This glassy phase tends to wet the ceramic particles. The phase continues to grow by dissolving residual ceramic particles. The liquid phase pulls the unmelted particles together, resulting in shrinkage and reduced water adsorption. Additionally, the presence of the glassy phase improves the mobility of the various oxides in the glaze during firing. This improved mobility helps homogenize the glass composition and enhances the rate of glass formation.

As the quantity of glassy phase increases because of the heat work, the viscosity of the glaze decreases and eventually the glaze becomes molten. The surface tension of the glaze allows it to wet the surface of the ware, which promotes adherence of the glaze to the ceramic surface. Once the glass is molten, degassing must occur to achieve a defect-free surface. Gases can be the result of incomplete decompositions in either the glaze constituents or the underlying body. Components of the ceramic body formulation, such as talc and carbonates, can contribute to gas evolution since they begin to decompose only after the glaze has begun to vitrify. Gas trapped between glaze particles or adsorbed on surfaces can contribute to bubble formation. Figure 6 shows an example of bubbles in a fired glaze.

On cooling, some species are not soluble in the glaze composition and precipitate crystals in the melt. The most common crystallization process that takes place is the precipitation of zircon crystals, which opacify the glaze. Precipitated opacifier crystals are visible under magnification as bright spots in the sanitary ware glaze. Crystallization of either alumina or other aluminates on cooling produces matte or satin glaze finishes. Other unintentional crystallizations, referred to as devitrification, can occur. These are mainly caused by a high level of alkalis or alkaline earth constituents in the glaze.

To impart color, pigments are added to the glaze composition. The array of pigments and their potential interactions are extensive. There are three methods of imparting color to a glaze:

1. For body colors in porcelains, finely ground transition metal oxides such as CoO (cobalt oxide), Cr₂O₃ (chromium oxide), and Fe₂O₃ are added to the glaze formulation. These metals dissolve into the glaze during firing. This method is not frequently used because of problems obtaining sufficient color intensity.
2. A second method for coloring glazes is to specially formulate the glaze, allowing colored crystals to precipitate from the melt on cooling.
3. Adding insoluble colorants to the glaze is the most common method for coloring glazes. The most frequently used pigments are doped zircon compounds, although a wide variety of synthetic spinels and other oxides are available. The doped zircon compounds are the most stable over a wide temperature range. Some examples of these colorants include (Zr,Pr)SiO₄ (yellow), (Zr,Fe)SiO₄ (pink or coral), and (Zr,V)SiO₄ (blue). These crystals are capable of small substitutions of transition metals into the Zr⁴⁺ sites in the crystal structure to achieve the desired colors.

Defects in Glazes

Several types of defects are observed in glazed ceramic ware. The defects are related to gas evolution from the ceramic ware or from the glaze constituents, thermal expansion mismatch, or the lack of adhesion of the glaze to the ceramic substrate.

Bubbles or pinholes in the glaze are the most common defect. They are more frequently observed in leadless glazes, because these glazes do not flow as well as the older leaded glazes. The gases can originate from decompositions taking place in the glaze components, from decompositions taking place in the body, or from the air trapped between particles in the glaze. To avoid these gas entrapments, thin applications are used to shorten the path that the bubbles have to travel to be expelled. More heat work or more fluid glazes at the firing temperature help in bubble removal. Alternatively, materials that decompose once the glaze is molten should be removed from the glaze or body composition. Examples of materials to avoid if gas evolution is a problem are lime stone and talc. Another approach is to prefire the ceramic ware before glazing. Double firing of wall tile is relatively common. An uneven surface texture can indicate that better firing or a more fluid glaze is needed.

Thermal expansion mismatch between the glaze and the body can result in crazing or peeling, depending on the type of mismatch. Commonly the glaze has a higher thermal expansion than the ceramic ware. In this event, the glaze shrinks faster than the ware on cooling, resulting in tensile stresses in the glaze. The tensile stresses can literally "pull" the glaze apart. Crazing is a pattern of cracks that radiate outward from the center of the ware. The tendency to craze can be corrected by using thinner glaze applications, which reduce stress accumulation, or by reducing the thermal

expansion of a glaze. Removing some of the alkali content of the glaze can reduce thermal expansion. In some cases, lithium is used to replace some sodium (or potassium) in the formulation to reduce thermal expansion.

Excessive dimensional change during the quartz inversion on cooling the ware can also result in crazing. Reducing the quartz content or reducing the particle size of the quartz can help minimize the crazing that results from dunting.

When the glaze has a lower thermal expansion than the ware, compressive stresses result. Excessive compressive stresses produce a defect known as peeling or shivering, where defects are a section of glaze that separates from the edge of the ware. The stresses can be corrected by using a thicker glaze application and increasing the thermal expansion of the glaze. Increased alkali content of the glaze typically increases the thermal expansion.

Adhesion defects known as crawling or tearing can result from several sources. These defects appear as irregular areas with poor glaze coverage. Drying problems with the glaze are a common source of adhesion defects. When the glaze has excessive shrinkage resulting from a very fine particle size or high clay content, the coating can tear. An organic binder can be added to improve the green strength of the glaze to reduce tearing. A minimum application thickness, clay content, and grinding will help reduce the tendency to tear. When there are multiple glaze applications, drying problems can result if adequate drying does not take place between the application layers. Surface contamination can interfere with the adhesion of the glaze to the surface and result in crawling. Green or bisque ware should be handled as little as possible to avoid contamination by dust or oils, for example. Finally, excessive levels of opacifier in the glaze can result in poor wetting of the ceramic ware by the glaze.

Foreign matter in the glaze can result in defects. Inadequately ground frit or granular contamination can result in surface irregularities. Metal contamination can result in discoloration. The source of the foreign matter should be identified and removed from the system. It is also possible for problems with the ceramic ware to show through the glaze. Large pyrite or marcasite (FeS₂) agglomerates in the clay can erupt through the glaze surface during firing. Typically, the source of the contamination can be identified by sectioning at the defect and examining the limited area of the defect (body or glaze) by microscopy. Chemical analysis of the contamination may also help identify the source of the defect.

ECONOMIC TRENDS IN NORTH AMERICA

Globalization and consumer preferences are causing rapid changes in the fine ceramics economic sector in North America. Globalization is placing pressure on manufacturing costs, and the volume of imported products is growing rapidly. This is, in part, based on new consumption patterns, with large quantities of products purchased through wholesale and retail outlets that are part of national chain stores. The purchasing policies of chain stores focus on price. For toilet bowls, nonclay refractory, and ceramic tile, the selling price is relatively high compared to the unit weight of the product, making importation economically feasible. By contrast, import penetration for lower valued products like clay brick is limited to land shipment from Mexico or Canada in North America (Table 7).

Changes in consumer preference have affected sales for some whiteware sectors, including fine china. As an example, previous generations preferred fine china for wedding gifts, but many people today prefer other consumer products.

Quality improvements in imported white ware products and product innovation have been factors in increased import growth. In sanitary ware, "one-piece" toilets and innovative glazes that reduce

Table 7. Estimated production and import statistics for North America for 2004

	Brick	Flat Glass	Toilet Bowls	Nonclay Refractory	Ceramic Tile
Annual domestic production increase, %	8.0	1.4	0.2	0	10–20
Current import percentage	<0.25	8	8	18	50+
Growth in market share by imports, %/year	≤1.4	–0.3	0 until 1998	2.2	2.7

home maintenance and provide a measure of protection from mold and bacteria are available with some imported products. These products provide added value for the consumer and the potential for additional profits for builders.

With sales of white ware products linked to slow population growth and housing starts in developed countries, the prospects for rapid market expansion appear to be limited. Growth in import percentages is likely.

Container Glass

Robert C. Freas

INTRODUCTION

Container glass, a mature product category that traces its roots back through more than 200 years, is distinguished from other glass industry sectors by both manufacturing method and end-use market. The container glass industry has undergone numerous technical changes in the past 30 years. For many years, glass containers were the primary packaging for beverages and most food products. Today, glass has been replaced in many of those markets with other competitive materials such as plastic, aluminum, and in some cases, polymer-lined cardboard containers. Yet in many applications and markets, glass holds its own, and in fact, the container glass industry has experienced a minor resurgence in recent years. Increases in container glass production and value have been very modest, averaging only 0.2% compounded annual growth over the last 5 years (Tincher 2004).

The container glass industry is of great importance to many industrial minerals producers. Glass manufacturing, including containers, consumes millions of metric tons of mineral raw materials annually, and may use up to 15 or 20 different mineral materials, depending on the specific glass batch requirement for the product being manufactured. The major mineral components consumed in container glass manufacturing are silica sand, soda ash (Na_2O), and limestone, although other minerals are also critical to the glass-forming process.

GLASS PRODUCTION

Glass containers are highly engineered products from both a structural and an aesthetic perspective. The design of the container includes multiple points of stress, which can be points of weakness and/or failure if there is an error in either the glass batch composition or the manufacturing process. On the aesthetic side, glass can be made in many colors and hues, but in most instances, it must be uniform throughout with no signs of bubbles or inclusions, which are frequently referred to as “seeds.”

In the glass-manufacturing process, raw materials are combined, or batched, before entering a throated furnace where they are melted together. Clark-Monks (1996) notes that this is the critical point, because the understanding and control of interdependent factors—starting with time/temperature relationships, consistent melting and forming properties, and consistency of raw materials—are the keys to furnace balance and quality control. The melting process follows a “critical current path” that represents the lowest temperature

and shortest time the molten glass will experience within the furnace and becomes the point at which the glass quality is defined. As noted in the discussion later on raw material, consistency in both the chemistry of each raw material and its particle-size distribution plays a critical role in the uniformity and consistency of the molten batch and the quality of the container produced.

The glass batch begins to melt at 600° to 900°C, and as melting continues, carbon dioxide (CO_2) and other gases are released, forming bubbles in the molten glass. The temperature of the batch continues to increase until it reaches approximately 1,300° to 1,400°C, although the temperature may vary depending on the type of furnace. Currently, about 25% of glass furnaces in the United States are newer-generation oxy-fuel systems (Tincher 2004) that are more thermally efficient in reaching and maintaining higher temperatures. This is important because the molten glass is refined at these higher temperatures. It is here that the last bubbles are driven off and the melt is in motion, becoming homogenized, which is critical to the uniformity of each container produced and to the elimination of slag or scum forming on or in the glass.

Once the glass has been refined, the temperature of the batch is cooled to 1,100°C to achieve the proper viscosity for glass forming. As the more viscous glass exits the throat of the melter, it flows to one of several forming machines. Here, a specific volume of glass, or “gob,” is metered from the melt. The gob is the molten glass required to form one container. Each gob drops into a mold where air is injected to form the “parison,” or preliminary shaped blank of molten glass. While still glowing hot, the glass is flipped and air is injected again to finish forming the container. The newly formed container is cooled to maintain its integrity, but it is not yet fully cooled nor structurally stable. Once formed, the glass moves to the annealing ovens where it is reheated slowly and then cooled at a specific rate to allow the stresses in the glass to stabilize (i.e., be relieved), thus preventing premature or excess breakage.

MANUFACTURING COMPANIES AND LOCATIONS

In the past two decades, the container glass industry has undergone extensive rationalization in the United States and throughout the world. Ball, Kerr, Diamond, and Thatcher—once household names as U.S. glass producers—no longer exist. Consolidation within the North American glass industry has left three primary container glass manufacturers in the United States—Owens-Illinois, Saint Gobain, and Anchor Glass Container—along with a limited number

Table 1. Container glass plants in the United States

Container Glass Plants	
Anchor Glass	Saint Gobain

Sapulpa, OK	

of small single-plant or specialty-glass manufacturers. The only new producer is Longhorn Glass in Houston, Texas, which is owned by Anheuser-Busch.

Anchor Glass Container, which operates eight glass plants, is the third largest producer of container glass in the United States. Over the years, Anchor acquired both Diamond Bathurst and Thatcher Glass before being acquired by Vitro (Mexico). Next, it was bought by Consumers Packaging of Canada before filing for bankruptcy. The company emerged from bankruptcy in 2001 as Anchor Glass Container Corporation and is now on solid financial

footing. Anchor Glass produces a diverse line of glass, including flint (clear), amber, and green containers for the food and beverage markets.

Owens-Illinois, formerly Owens Brockway after the acquisition of Brockway Glass in 1988, purchased the Canadian assets of Consumers Packaging, Inc., in 2001 and became the largest producer of glass containers in North America. Owens has 19 glass-production facilities in the United States, including the former Coors Glass plant in Colorado. The company is the only one of the three major U.S. glass producers to manufacture plastic containers; its Web site (www.owens-illinois.com) notes that they have 33 plastics plants in the United States and that plastics account for one third of corporate sales worldwide. Owens has been a leader in glass technology and recycling, reporting that 35% of its glass batch raw materials are from recycled glass. Outside of North America, the company's international container glass plants include facilities in several European and South American countries and China.

Saint Gobain, a French-owned company headquartered in Les Miroirs, France, is the second largest container-glass producer in the United States. In 1999, the company purchased Ball Glass (which had previously acquired Kerr Glass), along with the Foster Forbes Glass Division of American Can Company, and combined the two under the Saint Gobain name. Today the company operates 17 glass plants, producing a full array of container glass products. Saint Gobain's worldwide operations produce container glass, float glass, fiberglass, and ceramics (O'Driscoll 1977). The company's container-glass production facilities are located in the United States, Europe, and Brazil.

Other major non-U.S. producers of glass include Swedish-based Rexam PhC, one of the world's 10 largest packing producers (Kendall 1999). Rexam operates plants that produce glass, metal, and plastic containers. Rockware Glass Ltd. is the largest container glass producer in the United Kingdom, followed by TT Group PLC. Owens-Illinois, the world's largest producer of consumer packing, is one of the most dominant producers in Asia through its ACI Australian glass subsidiary and affiliated plants in Japan and China.

Although consolidation within the North American container glass industry has had an impact on industrial minerals producers, that is only part of the story. Many glass plants have closed in the United States, several of which were older, smaller, and less-efficient plants. Others represented excess capacity that could no longer be justified by the industry. At the same time, other plants were rebuilt, modernized, and expanded. Table 1 lists the locations of container glass plants in the United States.

CONTAINER GLASS MARKETS

For many years, the container glass industry experienced extensive competitive pressure from the aluminum can and plastics industries, particularly those that manufacture polyethylene terephthalate (PET) containers. Soft drinks and other beverages as well as numerous food and household products that were once packaged in glass are now marketed in plastic and/or aluminum. The key factors affecting the shift from glass to aluminum and plastic packaging are their light weight and ease of handling. The full impact on the container glass industry, which was at overcapacity both in North America and Europe, resulted in many plant closings during the 1980s. Plants continued to close through 2004, when Anchor announced the closing of its plant in Connellsville, Pennsylvania. The overcapacity also resulted in pricing pressure that ultimately led to consolidation in the industry.

For the last decade, U.S. container glass production has been fairly flat at 270 to 275 million units per year; the only segment

showing any real growth is the beer market. Kendall (1998) noted that glass shipments had increased nearly 25 % throughout the 1990s, and that apparent growth has continued into the early twenty-first century. Today, narrow-neck beer bottles account for nearly 60% of the container glass consumed. The growth in the beer bottle market has been offset largely by losses in other container glass markets as plastic continues to replace glass.

Although beer bottles have been the major bright spot for container glass producers, it is not without its challenges. Plastic beer bottles, which have been produced in Europe for more than 10 years, have now found limited acceptance in the United States. The key to producing plastic beer bottles is the co-extrusion of a barrier film that prevents the gas migration that causes the beer to become flat. Although several polymer systems have been used successfully, they are expensive and provide only limited shelf life for the beer. U.S. beer consumers have been reluctant to accept plastic beer bottles, so distribution has been limited to athletic stadiums and recreational beach locations where broken glass poses serious safety risks. Currently in the United States, it appears that plastic beer bottles will have a greater impact on the aluminum can market than on the container glass market.

Looking toward the future, the prospects for the container glass industry are positive. Rationalization is essentially complete, and most production facilities have been upgraded. More importantly, the trend from glass to plastic has slowed considerably now that the conversion of soft drink and milk packaging from glass to plastic is complete. Specialty ice tea and boutique beverages, along with the emergence of microbrewery beers, have had a positive impact on container glass consumption. That, combined with continuing growth in beer consumption, suggests that the market for glass containers has stabilized, and the market is actually growing at a modest 1.5% to 3.0% per year (Fredonia Group 1999).

RAW MATERIAL REQUIREMENTS

Each glass producer has its own formulation for the production of glass containers, and each includes high-purity silica sand as the primary batch raw material. Table 2 lists the general raw materials required for container glass, and Table 3 shows a typical composition for container glass as oxides. It is critical in the manufacture of container glass that all mineral raw materials be consistent in both chemical composition and particle-size distribution. Four excellent articles on raw materials for container glass are Lines (2004); Kephart, Pool and Ryder (1986); Lavender (1988); and Vogel (1985).

Silica (SiO_2) is the basic building block in glass formation. As the dominant oxide in glass, it provides much of the body bulk. Silica must have a minimum value of 99.0% SiO_2 ; some specifications may require a minimum of 99.5% SiO_2 . High-purity quartz sand is the primary source of silica in the glass batch. Several of the other batch raw materials, however, include small amounts of silica that must also be accounted for in the batch. Some glass formulations, particularly where high thermal shock or chemical resistance are critical to end use, require a very small amount of borosilicate that can be added with the silica sand.

Soda ash, the second most common ingredient in container glass, is the predominant glass modifier. As a modifier, Na_2O acts as a flux that allows the melting point of the batch to be approximately 200°C lower. An additional benefit is that the lower temperature extends refractory life.

Limestone contributes calcium oxide (CaO) to the batch, which modifies the glass, increasing its strength and resistance to abrasion. Much of the value of the limestone is realized during the annealing phase of glass production. Most limestone specifications require a

Table 2. Raw materials required for container glass

Raw Material	Percentage

CaO	10
Al_2O_3	2
SO_4^*	1

* Sulfate from salt cake or gypsum.

minimum of 97% calcium carbonate (CaCO_3) and a maximum of 0.12% iron oxide (Fe_2O_3).

The specification for iron in limestone for standard container glass is 0.12% Fe_2O_3 ; however, there are several specialty-glass producers with a lower maximum iron specification of 0.04% Fe_2O_3 . These producers make very clear flint glass and/or crystal and cannot tolerate iron discoloration. Traditionally they use aragonite with low iron from the Bahamas, but this source was sold and aragonite production was curtailed sharply in late 2003.

Feldspar is the most common source of alumina (Al_2O_3) for glass production, although in many instances nepheline syenite is used instead. Alumina is an important glass modifier, and its inclusion in the batch increases durability of the glass and reduces its tendency to devitrify.

Several minerals are used as coloring agents or chromophors in container glass. Clear, or flint glass, may be tinted for reasons of both function and appearance. When tinting is required, the following elements commonly are used to produce specific colors:

- Green—chromium and iron
- Yellow—chromium, vanadium, and cadmium
- Blue—cobalt and iron
- Amber—iron
- Red—selenium

Other minerals may be used in container glass formulations to assist in developing other specific properties, particularly for specialty containers (e.g., containers that require an opacifier to be added). The chapter on Specialty Glass presents an excellent discussion on the use and application of these minor constituents.

As mentioned previously, the chemical and physical consistency of batch raw materials is vital to quality glass production. It is necessary to maintain homogeneity in molten glass and to sustain constant, uniform viscosity throughout the glass-forming process. Medalyer (1996) notes that the homogeneity of glass is affected by both the chemical uniformity of batch raw materials and their moisture levels. Because raw materials are blended on the basis of weight evaporation, moisture can affect the composition of glass during melting.

Cullet, or recycled glass, is an ingredient used in most glass batches. Bottle laws and environmental initiatives on recycled

content have mandated that more cullet be employed in batch raw materials. The amount of cullet being handled and blended varies significantly from one glass plant to another (Rosenthal 1996). But from a minerals standpoint, the greater the content of cullet, the lower the requirement for natural mineral raw materials.

SUMMARY AND CONCLUSION

Glass container production in the United States and throughout the world has declined as other types of packaging have replaced glass. Nevertheless, the industry has now stabilized and is growing at a very modest rate. As glass container producers look ahead, three major issues receive the most attention: container weight, increased melting and energy efficiencies, and ever-changing environmental laws and requirements.

As plastic competes with glass, and as bottles are recycled rather than refilled, container weight receives more attention. A container weighing less means reduced wall thickness and less glass by volume. As the wall thickness decreases, stresses within the glass container increase and durability and strength suffer. Minerals producers are concerned that decreasing container weight will result in a decrease in the volume of minerals that the producer requires.

Because energy is a major cost component of glass manufacturing, melter efficiency has been the focus of industry research for many years. Future goals of the industry leaders for 2020 are (1) reduction in production cost to 20% below 1995 levels, (2) reducing energy use by 50% below 1995 levels, and (3) reducing air and water emissions by 20% below base-year levels (Tincher 2004). These goals can be met with aggressive technological innovations such as the oxy-gas-fired submerged combustion melter; (Greenman 2004).

The manufacture of glass requires melting of a number of raw materials that, when thermally altered, emit various compounds in the atmosphere. Major emissions include CO₂, sulfur, and nitrous oxides with lesser amounts of hydrochloric acid, hydrofluoric acid, and carbon monoxide.

Norman and Shulver (1999) present a complete discussion of these emissions along with a discussion of other impacts on the glass industry. Emphasis on environmental quality has been ongoing in both the United States and Europe, with the U.S. Environmental Protection Agency (EPA) emphasizing the use of best available control technology (BACT). BACT will have associated costs that most likely will increase the focus on using recycled glass to reduce emissions from unmelted natural raw materials, but the full impact of this has yet to be determined.

In conclusion, the supply of industrial minerals materials to the producers of glass containers represents a very high-volume market. The container glass market is a mature market that is stable to slowly growing. As industrial minerals producers recognize container glass as a major market for their products, they must be ready to maintain consistently high-quality specification standards because these standards will probably increase over time. The move to lightweight containers and the increased use of cullet will reduce the volume of raw materials consumed, but the demand for higher-quality industrial minerals will exist for many years to come.

Fiberglass

Kevin Schaal

INTRODUCTION

It is estimated that there are about 600 glass-melting furnaces operating in North America. These furnaces produce glass for a variety of products ranging from architectural and automotive glass, glass containers, and specialty glass to fiberglass. Of the 600 furnaces, approximately one-sixth produce fiberglass, including both insulation glass and textile glass.

Insulation and textile fiberglass are differentiated on the basis of their end use, the raw materials used and their specifications, and to a somewhat lesser degree by the manufacturing methods employed to produce these two products. This chapter discusses the manufacture of fiberglass, the raw materials required, and the end-use markets for both insulation-grade and textile-grade fiberglass.

GLASS-MAKING FURNACES

Glass furnaces are generally first categorized by the fuel sources used to heat them. Some furnaces are heated electrically, others are heated by the combustion of natural gas or propane, and in many cases, combustion and electric boost are used in combination. Combustion-heated furnaces are further categorized by the method used to recover heat from the exhaust gas stream, and by whether air or oxygen is used in burning the fuel.

The use of oxygen in place of combustion air is one of the more recent developments in the fiberglass industry and is becoming widely accepted and highly successful. When oxygen is used, an oxygen-generating plant is often constructed on site in the general vicinity of the glassmaking furnace. In cases where the glass furnace is smaller in size, tanker trucks make deliveries of oxygen.

When the furnace is heated with natural gas and combustion air, it is common to recover some of the waste heat from the exhaust gas with a recuperator or less often with a regenerator. Recuperators are heat exchangers in which the outgoing hot waste gases transfer some of their energy to cold air needed for combustion by transfer through metal or ceramic pipes. In a regenerator, the waste gases pass through a chamber in which refractories are stacked in such a way that the hot flue gases pass between them and the rebuy transfer some of the thermal energy to the refractories. After about 20 minutes, the flue gases are diverted through an alternative chamber while cold air is passed through the first chamber in the reverse direction, thus absorbing thermal energy. The air then passes as preheated combustion air to the burners.

When the furnace is heated with natural gas but oxygen is used in place of combustion air, the volume of exhaust gases is reduced by approximately 80%, making it uneconomical to install and operate a recuperator or a regenerator.

For electrically heated furnaces, current can be passed through the glass bath using submerged electrodes made from metallic molybdenum, because glass at elevated temperatures is electrically conductive. The electrode-holders are water cooled on the cold face of the furnace to prevent the molybdenum from overheating, as molybdenum oxidizes rapidly when temperatures exceed 600°C (1,112°F). Electrodes can be inserted into the furnace from the top, the bottom, or through the side walls. Electrodes are slowly consumed in the process of melting the glass, making it necessary to add replacement electrodes periodically. Electrodes come supplied with threaded ends so replacement electrodes are screwed into the end of the existing electrodes and pushed into the glass bath.

Operating glass furnaces produce from as little as several metric tons of glass per day to upwards of 227 tpd. The dimensions of the larger furnaces might be 18 m (60 ft) long by 6 m (20 ft) wide, with a glass depth of slightly more than 1 m (40 in.). Smaller all-electric furnaces might be 2 to 3 m (6.6 to 9.8 ft) in diameter and hold 0.6 m (24 in.) of glass. The life of a combustion-fired furnace can be as long as 7 or 8 years, whereas the life of an all-electric furnace, depending on design, can be as short as 6 months. One advantage to a small all-electric furnace is the short length of time required to re-brick a furnace. For some furnaces, the glassmaking operation can be resumed in as few as 24 hours.

Charging of mixed batch to the furnace is usually accomplished through the use of feed screws or augers that deposit the well-blended ingredients directly onto the surface of the molten glass. As the batch melts and moves downstream, the glass is often stirred or agitated by the use of bubblers pulsing air or oxygen into the glass from the bottom of the melter via metal bubbler tubes.

The glass exits the melter into a refining chamber or into distribution channels or a forehearth that directs the glass to the device used to convert it to fibers.

FIBERIZATION TECHNOLOGIES

Rotary Fiberization

Rotary fiberization uses a metal disc with multiple rows of holes precisely drilled around the circumference of the disc. Hot glass

enters the spinning disc and centrifugal force causes the hot liquid glass to exit the holes in the form of fine, discontinuous fibers required for insulation products. Additional attenuation is accomplished by putting the fibers in the path of a high-velocity stream of air or combustion gases. Next, liquid binders are applied, and the fibers are collected in a vacuum box in the form of a blanket. Binders are cured by passing the glass mat containing the uncured binder through an oven. The average diameter of fibers produced by the rotary process ranges from 2 to 6 μm , with the diameter distribution running from submicrometer to as high as 20 μm . The velocity of fibers exiting the rotating spinner is in the range of 150 m per sec (500 ft per sec) and the throughput of one spinner can be as high as 1,135 kg per hr (2,500 lb per hr).

Flame Attenuation

Flame attenuation fiberization is one of the oldest techniques used to make fiberglass insulation products. The flame attenuation process is sometimes referred to as the pot and marble process. In this process, glass marbles are melted in small-volume, cylindrical-shaped Inconel pots. The pot bottom contains concentric rings of holes from which a primary glass fiber, approximately 1 mm in diameter, are drawn. Secondary attenuation occurs when the primary fibers are carefully placed in front of a high-temperature, high-velocity burner. The flame breaks the filaments into long fibers with a narrow diameter distribution that then pass through the binder spray. Fibers less than 0.5 μm in diameter can be produced by this process. The drawbacks of the flame attenuation process are that it is very inefficient in terms of energy consumption and the production rate per pot hour is very low.

Continuous Process

Textile fibers produced by the continuous filament process are made by drawing molten glass through orifices in platinum-alloy bushings and then rapidly pulling them to reduce their diameters to the prescribed size. Each orifice ranges from 0.8 to 3 mm (0.03 to 0.12 in.) in diameter and bushings have been constructed with as many as 6,000 orifices producing at a rate of more than 210 kg per hr (460 lb per hr). A bushing is heated by the hot glass entering it from the glass distribution channel and by supplemental heat applied electrically. The individual filaments from each bushing orifice are gathered into one strand or bundle, which is then either chopped into discrete length pieces from 3 mm to 50 mm ($1/8$ in. to 2 in.) long by a mechanical chopper or wound into cakes by filament winders. These mechanical devices operate at speeds up to 120 m per sec (394 ft per sec) and result in fiber having diameters that range from 3 to 20 μm . Because glass filaments are highly abrasive when rubbed against one another, size coatings are applied to the individual filaments before the strand is gathered to minimize degradation of strength. An integral part of the bushing design is cooling fins or water-circulating cooling tubes that extract heat from the bundle of fibers as they exit the bushing orifices and before the size coatings are applied.

RAW MATERIALS USED IN THE MANUFACTURE OF FIBERGLASS

Overview

The major criteria for selecting raw materials for the manufacture of fiberglass are composition and particle size. With respect to composition, purity and consistency need to be closely evaluated. The fiberglass producer must be able to make a glass that is compatible with its fiberizing process and that has excellent consistency in the short term as well as over days and weeks. To accomplish the

necessary degree of consistency of the glass composition, it is necessary that the starting raw materials have an equivalent degree of consistency. With respect to purity, if a particular raw material is slightly less pure but has excellent consistency, the fiberglass producer will often be able to compensate for that impurity by adjusting the quantity of other batch ingredients used.

In terms of impurities, iron oxide receives a high level of attention. Iron oxide present in the glass in the reduced form as FeO plays a major role in how the glass is able to transmit radiant energy. In most fiber-producing processes, it is desirable to limit the amount of FeO, so this places a limit on the iron oxide content of the starting raw materials. The level of organic matter present in a glass raw material is also important. Organic matter acts as a reducing agent to the glass and reduces iron oxide from the oxidized state, Fe_2O_3 , to the reduced state, FeO, which has already been noted as undesirable from a heat transmission point of view.

Other impurities of concern that need to be minimized or eliminated are hazardous elements that are volatile, particularly during the batch melting process. Arsenic, mercury, selenium, and the like are included in that list. Additionally, refractory minerals that are hard to melt in the glass are undesirable. These minerals include anorthite, beryl, tourmaline, garnet, corundum, ilmenite, rutile, and zircon.

In considering the specifications for the particle-size distribution of glass batch raw materials, the fiberglass manufacturer needs to have materials that exhibit good flow properties so that feeding materials into and out of storage silos is done without material bridging over the silo discharge opening. Good flowability is also necessary so that the material can be weighed accurately as the glass batch is being prepared. It is also important that no single material segregates from the other materials in the batch during blending and conveying. Finally, the materials need to be small enough in size so that they melt in the allotted time and at the operating temperature of the glass-melting furnace, but yet not so small that excessive dust is generated in the batching and unloading operation.

For the raw materials that supply silicon dioxide (SiO_2) and aluminum oxide (Al_2O_3) to the glass, there must be a limit to the amount of the coarsest particles present in the raw material. For these materials, the fiberglass manufacturer will want to limit the amount of material greater than about 425 μm (40 mesh) to not more than 2% by weight. For controlling dust in the batching process, the amount of material finer than 75 μm (200 mesh) is limited to not more than about 2%.

For other materials that are not as difficult to melt, such as the alkali, alkaline earth, and borate minerals, there is not as stringent a requirement on coarse particles. The particle-size distribution that imparts the best flow properties to these materials is more important, as is making sure that the particle-size distribution of the entire mixed batch is cohesive and not prone to having one or more materials segregate from the other materials.

RAW MATERIALS USED IN THE MANUFACTURE OF INSULATION FIBERGLASS

Silica Sources

Silica is present in the highest concentration of any oxide in the glass formula. As the backbone of the glass structure, it takes on great importance. Sands that are used to supply this oxide are therefore equally important. Sands used in the manufacture of insulation fiberglass are categorized into two classes: glass sands and feldspathic sands. Glass sands are very high in quartz content with some minor clay-bearing minerals present as contaminants. They have a SiO_2 content of 99% or higher, with SiO_2 being held between $\pm 0.4\%$ of

the nominal value. The Fe_2O_3 content can be as low as 0.025% and cannot vary by more than $\pm 0.02\%$ – 0.03% . Feldspathic sands, which are combinations of quartz and feldspar, consequently have SiO_2 contents that are less than those for glass sands and Al_2O_3 contents as high as 8% to 12%. Feldspathic sands are generally characterized by higher concentrations of iron oxide, and the chemical composition is less consistent overall. For feldspathic sands, the iron oxide content can be as high as 0.25%. Other oxides that accompany feldspathic sands are sodium oxide (Na_2O), potassium oxide (K_2O), or calcium oxide (CaO), depending on the type of feldspar present in the deposit. Na_2O can range from about 1.5% to 5%. K_2O can be present from about 2% to 4.5%, and CaO is generally present at levels of less than 1%.

The fiberglass manufacturer will set limits to the particle-size distribution of the silica source independent of whether it is glass sand or feldspathic sand. The primary requirement is to limit the quantity of coarse particles so that the sand completely melts in the glass furnace at the furnace melting temperature and in the length of time it spends in the furnace. The second requirement is to limit the fine particle-size fraction for dust control during the material unloading step. The limit on the coarse particles is generally no more than 1% to 2% as coarse as 425 μm (40 mesh), with only a trace allowed as coarse as 600 μm (30 mesh). The limit on the fine end of the particle-size distribution is no more than 1% to 2% finer than 75 μm (200 mesh). The trend for sand specifications with respect to particle size is to seek finer and finer sands.

Borates

The most commonly used borate minerals in the manufacture of insulation fiberglass is 5-mol borax. The composition of 5-mol borax is $\text{Na}_2\text{B}_4\text{O}_7 \times 5\text{H}_2\text{O}$. It is produced from tincal ore that is mined in the California desert, in central Turkey, or from solution mining operations in Searles Valley, California. Five-mol borax is the preferred source for adding boric oxide (B_2O_3) to the fiberglass composition because it is very highly refined, which gives it high purity and consistency. The B_2O_3 content of 5-mol borax is consistently 49% with Na_2O being 21.7%. It contains 5 molecules of chemically combined water that comprises 29.3% by weight.

Ulexite is also used as a source of B_2O_3 to fiberglass compositions. Ulexite is a sodium, calcium borate mineral, mined in Turkey, having the approximate composition of 37% B_2O_3 , 6% Na_2O , 17% CaO , and lesser amounts of SiO_2 , Al_2O_3 , and magnesium oxide (MgO). The major oxides, B_2O_3 , Na_2O , and CaO , are all controlled within $\pm 1\%$ of their nominal values. For the equivalent amount of B_2O_3 , 25% more ulexite must be used compared to 5-mol borax. Additionally, because ulexite is a less highly refined material, its chemical consistency is poorer than 5-mol borax. The amount of chemically combined water in ulexite is about 34%.

Because borate minerals are not particularly refractory in nature, there is less concern about ease of melting in the glassmaking furnace, so the limits set on the coarse particles are not as stringent. Particles as coarse as 1,400 μm (12 mesh) are commonly seen in both 5-mol borax and ulexite. Again, dust control is of concern, so the amount of particles finer than 75 μm (200 mesh) is ideally limited to a few percent.

Alkali

The alkali oxides, Na_2O , K_2O , and lithium oxide (Li_2O), are classified as modifier oxides in the glass structure. They are added to the glass formula because they serve as fluxes for melting the more resistant quartz grains. The primary alkali oxide used by fiberglass manufacturers is sodium oxide, but there are occasional needs for potassium or lithium oxides. Soda ash is almost universally used to

supply sodium oxide to the glass. Potassium carbonate is used to supply potassium oxide, and either lithium carbonate or spodumene is used to supply lithium oxide.

The chemical composition of soda ash is Na_2CO_3 . Most domestic soda ash is produced from trona ore deposits in the Green River, Wyoming, area with lesser amounts produced from solution mining operations in Searles Valley, California. Soda ash is highly refined and chemically consistent, so the ability of the fiberglass manufacturer to closely control the sodium oxide content of the glass is excellent. In melting, the carbon dioxide in soda ash is evolved as a gas and leaves sodium oxide to enter into the glass structure. Soda ash contains 58.4% Na_2O and 41.6% carbon dioxide (CO_2).

In some specialty fiberglass compositions, potassium carbonate or potash is used to supply K_2O to the glass. The chemical composition of potassium carbonate is K_2CO_3 . In melting, the carbon dioxide in potash is evolved as a gas and leaves potassium oxide to enter into the glass structure. Potassium carbonate contains 67.5% K_2O and 32.5% CO_2 . As is soda ash, potassium carbonate is a highly refined and very consistent material.

Potassium oxide is added to the glass because—when used in conjunction with sodium oxide—it provides a more complex glass structure, which is beneficial in preventing alkali ions from leaching from the glass surface when exposed to liquids.

Lithium oxide is touted as a melting aid in glass batch formulations and is seeing some application within the industry. When used, Li_2O is typically added to the glass in concentrations of 0.2% to 0.4% by weight with either lithium carbonate or spodumene used as the source of this oxide. The use of lithium oxide has been reported to increase the capacity of a given furnace by as much as 10%, or instead of pulling the glass furnace at the higher daily throughput, significant energy reductions have been realized. There is debate about whether lithium carbonate or spodumene is the more effective melting aid. Lithium carbonate contains 40% Li_2O , with the balance being CO_2 . Glass-grade spodumene contains 5% Li_2O , with the balance being made up of 75% SiO_2 , 18% Al_2O_3 , and less than 0.5% of Na_2O and K_2O .

As with the borate minerals, alkali-bearing minerals are not particularly refractory in nature. Concern with difficulty of melting in the glassmaking furnace is diminished, so the limits set on the coarse particles is not as stringent. Particles as coarse as 600 μm (30 mesh) are commonly seen in these materials. Dust control is again required, so the amount of particles finer than 75 μm (200 mesh) is ideally limited to several percent. Sizing the alkali materials to match the particle-size distribution of the other batch ingredients to avoid material segregation is another important consideration.

Alkaline Earth

Alkaline earth oxides are added to a glass formula to serve as stabilizers within the glass structure, imparting chemical durability to the glass. For insulation fiberglass, limestone or quicklime is used to provide CaO to the glass. Limestone, CaCO_3 , is converted to quicklime by burning the CO_2 out of the raw stone in a high-temperature calcining operation. Limestone generally needs to have a purity level of 97% or higher with a resultant CaO content of 54.5% that is generally consistent to within about $\pm 0.4\%$. Limestone may contain MgO up to about 1% and Fe_2O_3 as high as 0.5%; however, glassmakers generally prefer to limit the iron oxide to no more than about 0.1%. When these limestones are converted into quicklime by calcining, they contain 95% or more CaO , allowing for a 2% to 3% residual loss on ignition (LOI) from incomplete burning.

Dolomite or dolomitic quicklime is used to provide MgO to the glass. Again, the purity level needed for dolomite is 97% or

higher, which results in a CaO content of about 43.7% and an MgO content of about 31.4%. When these dolomites are converted into dolomitic quicklime, the CaO content is about 57% and is consistent within $\pm 0.8\%$, and the MgO content is about 40% and is consistent within $\pm 0.4\%$. The residual LOI from incomplete burning is 2% to 3%. These materials may have iron oxide contents as high as 0.5%, but glassmakers generally prefer iron oxide to be no more than 0.1%.

The glass composition determines the ratio of limestone to dolomite that will be required in the batch formulation. If the glass composition requires less than about 1% MgO, it is likely that only limestone will be used. If the glass composition requires more than about 1% magnesium oxide, a corresponding amount of dolomite will be required.

Limestones and dolomites comprised of material as coarse as 2,000 μm (10 mesh), but not more than about 10% finer than 150 μm (200 mesh), are specified by the fiberglass manufacturer. For quicklime and dolomitic quicklime, the raw material specifications are closely negotiated with the supplier. Calcining limestone and dolomite results in a softer, more friable, and finer material that tends to be dependent on the calcining process and the downstream materials handling system. These materials are frequently more difficult for the fiberglass manufacturer to handle, and at times, flow aids are added to improve their handling characteristics. Although the fiberglass manufacturer would prefer less of the fine fraction, the supplier is not always able to accommodate that need.

In some special circumstances, processed magnesium oxide is used in place of dolomites. In that case, the fiberglass manufacturer must ensure that the magnesium oxide is not so refractory or too coarse that it will not adequately melt under the time-temperature conditions of the melting furnace.

Alumina

Aluminum oxide falls into the class of stabilizer oxides, similar to the alkaline earths, and imparts chemical durability to the glass. Al_2O_3 is generally supplied to a fiberglass composition through the use of feldspar, nepheline syenite, or aplite. These materials are combinations of sodium, potassium, or calcium aluminosilicates. Albite is the sodium feldspar end member, and microcline and anorthite are the potassium and calcium feldspar end members, respectively. The approximate Al_2O_3 content of feldspar is 19% and is consistent to approximately $\pm 1.0\%$. Nepheline syenite is a quartz-free rock consisting mostly of nepheline and feldspar. It has approximately 23.5% Al_2O_3 and is consistent to approximately $\pm 0.4\%$. Aplite is light-colored igneous rock with the same mineral composition as granite but with a fine-grained texture. Aplite contains 21.5% Al_2O_3 and is consistent to approximately $\pm 0.7\%$. Aplite also contains trace amounts of titanium dioxide (TiO_2) and phosphorus pentoxide (P_2O_5). The iron oxide content of these materials ranges from about 0.05% to about 0.2%, with feldspar being the lowest and aplite being the highest.

The feldspathic sands described earlier are also used to provide Al_2O_3 to the glass. The particle-size requirement for these materials is essentially the same as that for sand.

Zinc Oxide

In specialty fiberglass compositions used to produce liquid filtration media that requires a very chemically resistant glass, granulated zinc oxide (ZnO) is added to the glass composition. The zinc oxide used for this purpose is generally 98% pure or greater.

Barium Carbonate

Barium oxide (BaO) is added to some specialty fiberglass compositions by the use of barium carbonate (BaCO_3) as a batch ingredient.

These glasses are used for making liquid filtration media where producing a chemically resistant glass is important. The barium carbonate used for this purpose is generally 95% to 98% pure. The primary contaminants found in barium carbonate are strontium carbonate and sodium carbonate, and they are present in concentrations of approximately 2% and 1%, respectively.

Fluorspar

Fluorspar is used as a flux in certain glass formulations. Typically, fluorspar will have a purity level of greater than 97% calcium fluoride (CaF_2) with a limit on the Fe_2O_3 content of less than 0.1%. Trace impurities like SiO_2 , Al_2O_3 , MgO , and CO_2 are found. Many glass companies have successfully removed fluorine (F_2) from the glass composition following regulatory decisions preventing its use. Fluorine is a particularly volatile element in the glass. It is not unusual for nearly 50% of the added fluorine to be lost as a result of evaporation or volatilization.

Sodium Sulfate

In many fiberglass compositions, a minor amount of sodium sulfate, commonly called salt cake, is added as a refining agent to aid in the removal of seeds and blisters. Salt cake has two other functions in the glass. When molten, it functions as a surfactant, wetting grains of sand to assist in their melting. It also functions as an oxidizing agent, acting to offset some of the reductants found as contaminants in glass batch raw materials. In some cases, barium sulfate might be substituted for sodium sulfate.

Cullet

Many insulation fiberglass batches use some percentage of recycled glass, called cullet. Most of the cullet available for use as a batch ingredient is from recycled bottles or recycled plate glass. ASTM D5359 describes the industry-accepted specification for cullet. Both bottle and plate cullet are soda-lime-silica glasses, so the oxides supplied from cullet need not be supplied from the other batch ingredients. The use of cullet in a fiberglass composition will lessen the requirement for sand, soda ash, and limes or limestones. The particle-size requirement from the ASTM specification is that cullet shall be smaller than 6 mm ($\frac{1}{4}$ in.) in size and can contain no more than 15% finer than 75 μm (200 mesh).

Synthetic Minerals

A recent development in the fiberglass industry is the availability of manufactured minerals in the family of calcium and calcium-magnesium silicates. These materials are manufactured by spray-drying fine silica sands, together with quicklime or dolomitic quicklime, to form the precursors of diopside ($\text{CaMgSi}_2\text{O}_6$) or wollastonite (CaSiO_3), respectively. These materials, when heated rapidly upon entry in to the glass furnace, convert completely to diopside or wollastonite because of the intimate contact of the mineral particles and the heat of the furnace. The reported advantage to these materials is that the melting reactions take place faster so that more glass can be produced per day for a given furnace or so that melting energy can be reduced. These materials are effective because, with their use, the quantity of coarser-grained sand is reduced, and the resultant ratio of flux to quartz particles is increased.

RAW MATERIALS USED IN THE MANUFACTURE OF TEXTILE FIBERGLASS

Overview

One fundamental difference between insulation fiberglass and textile fiberglass made by the continuous filament process is the glass composition. E-glass, the historical industry standard for textile

Table 1. E-glass definitions from ASTM D578-00

Chemical	E-Glass for General Applications, wt %	E-Glass Used in Aerospace and Printed Circuit Boards, wt %
B ₂ O ₃	0–10	5–10
CaO	16–25	16–25
Al ₂ O ₃	12–16	12–16
SiO ₂	52–56	52–56
MgO	0–5	0–5
Alkali*	0–2	0–2
TiO ₂	0–1.5	0–0.8
Fe ₂ O ₃	0.05–0.80	0.05–0.40
Fluoride	0–1.0	0–1.0

* For general applications, alkali is defined as Na₂O + K₂O + Li₂O. For aerospace and printed circuit boards, alkali is defined as only Na₂O + K₂O.

fiberglass, is limited in an alkali content to a maximum of 2%, as defined in ASTM D578-00). In this standard, ASTM makes a distinction between glass compositions used for general applications and those used in aerospace and printed circuit board applications. Table 1 shows the allowable glass compositional ranges for each of these categories.

The two most significant differences between the general use category and the aerospace and printed circuit board category are the allowable level of boric oxide and the inclusion of lithium oxide as one of the alkali oxide members. For general use applications, E-glass can now be free of boric oxide, and lithium oxide is included in the definition of total alkali. Owens Corning fiberglass's patented Advantex composition contains no boric oxide. For textile fiberglass sold into aerospace applications and for printed circuit boards, E-glass must contain between 5% and 10% B₂O₃ and the use of Li₂O is prohibited.

In addition to the low level of alkali oxides found in E-glasses, they have Al₂O₃ and CaO contents significantly higher than insulation fiberglass compositions. In E-glasses, Al₂O₃ typically ranges from 12% to 16%, and CaO can be as high as 23%, whereas in insulation glasses the Al₂O₃ content is generally less than 5% and the CaO content is generally between 5% and 10%. Silica, however, is still the most prevalent oxide in E-glasses, and as the backbone of the glass structure, it takes on great importance.

Silica

The most critical raw material for the manufacture of textile fiberglass is the silica sand source. Because the glass composition is limited in allowable alkali content as described previously, the glass is much harder to melt than an insulation fiberglass composition. Furnaces melting these glasses operate at temperatures that are hundreds of degrees higher than those found in furnaces melting insulation glass compositions. In order for furnaces melting E-glass to produce a daily quantity of high-quality glass large enough to be economically viable, it is necessary for the particle size of the silica source to be finer than that of insulation glasses. Stated another way, unless the silica sand is much finer in particle size than that used in insulation glasses, the furnace pull rate would be so low as to be financially impractical.

The fiberglass manufacturer will specify that the silica supplier grind or mill the sand into silica flour with a particle-size distribution having 90% or more of the particles smaller than 45 µm (325 mesh), with essentially no particles as coarse as 250 µm

(60 mesh). The chemical requirements of the ground silica are essentially the same as those for glass-grade sands used for insulation fiberglass; the SiO₂ content is greater than 99% and must be held between ±0.4% of the nominal value. The Fe₂O₃ content is generally less than 0.1% and cannot vary more than ±0.03%. Trace impurities that are refractory in nature and will not melt in the glass furnace are unacceptable, similar to what was described for sand usage in insulation glasses.

Borates

Where the glass composition calls for the inclusion of B₂O₃, boric acid, colemanite, and 5-mol borax are the minerals usually specified.

Boric acid has the chemical composition of H₃BO₃. The B₂O₃ available to enter the glass structure is 56%, with the balance being chemically combined water. Colemanite is a naturally occurring calcium borate mineral that contains from 25% to 28% CaO and 41% to 43% B₂O₃, with impurities of SiO₂, Al₂O₃, Na₂O, MgO, and strontium oxide (SrO) that range from 0.2% in the case of sodium oxide to more than 4% for SiO₂. Because colemanite is lower in B₂O₃ than boric acid, and because it is less highly refined and contains more impurities, many fiberglass manufacturers prefer boric acid over colemanite. One advantage that colemanite has over boric acid is it contains a lower amount of chemically combined water, 25%, versus 44% for boric acid.

Five-mol borax was described in the section on insulation fiberglass. Because 5-mol borax contains 21.7% sodium oxide, and because textile fiberglass compositions are limited in the allowable alkali content, the use of 5-mol borax as a batch material is limited. For a general purpose E-glass composition where the B₂O₃ content can be as high as 10%, however, a typical batch will employ two of the borate minerals in a mixed-borate formulation. The practice is to add 5-mol borax until the sodium oxide requirement of the final glass composition is satisfied. Then either boric acid or colemanite is used to satisfy the balance of the boron content of the glass.

Alkali

Because alkali oxides in textile glass compositions are limited to 2% or less, the use of alkali-containing minerals is much lower compared to glasses used to produce insulation fiberglass. Five-mol borax or soda ash can be used to supply the limited alkali content of these glasses. In cases where lithium oxide is added, the practice described in the section on insulation fiberglass is applicable for E-glasses as well.

Alkaline Earth

For textile fiberglass, limestone or quicklime is used to provide CaO to the glass, and dolomite or dolomitic quicklime is used to supply MgO. The chemical requirements described in the section for insulation fiberglass are applicable to textile fiberglass as well.

The requirement for the particle-size distribution of limestone used in the manufacture of textile fiberglass is generally that 80% of the product must be finer than 75 µm (200 mesh), and less than 1% can be as coarse as 250 µm (60 mesh). For quicklime or dolomitic quicklime, the particle-size requirements described in the section on insulation fiberglass apply here as well.

Alumina

In the manufacture of textile fiberglass, the primary source of Al₂O₃ is air-floated kaolin produced in the southeastern United States. It is the preferred source of Al₂O₃ because it is low in alkali content and is consistent with the requirement that the glass be low in alkali. Kaolin clay contains 45% SiO₂, consistent within ±0.5%, and 38.5% Al₂O₃, also consistent within ±0.5%. The particle-size

Table 2. Composition ranges, descriptions, and uses for other textile fiberglass compositions

Oxide	C-Glass, wt %	D-Glass, wt %	E-CR Glass, wt %	AR Glass, wt %	R-Glass, wt %	S-2 Glass, wt %

Descriptions and Uses						
C-Glass	D-Glass	E-CR Glass	AR Glass	R-Glass	S-2 Glass	
Chemical stability in corrosive acid environment	Low dielectric constant for electrical applications	Where strength, electrical resistivity and acid corrosion resistance are needed	Alkali resistant glasses for reinforcing cement and concrete	For reinforcements where added strength and acid corrosion resistance are needed	High strength, modulus, and stability under extreme temperature and corrosive environments	

requirement for kaolin clay is that 97% or more must be finer than 45 μm (325 mesh). By convenience, this nearly matches the particle-size distribution of the ground silica. This means that two of the major raw materials for textile glasses are similar in particle-size distribution. This is beneficial in preventing batch segregation in mixed batches. Trace amounts of TiO₂ and K₂O are present in clay, as well as iron oxide. TiO₂ can be as high as 1.7% and K₂O can be as high as 0.3%. Low-iron clays would be defined as having an iron oxide content as low as 0.5%; in high-iron clays, Fe₂O₃ may approach 1%. The supplier must control the iron oxide content of the clay to approximately $\pm 0.05\%$ of the nominal value.

Fluorspar

Fluorspar is also sometimes used in the manufacture of these types of fiberglass compositions, and the requirements are essentially identical to those outlined in the section on insulation fiberglass.

Iron Oxide

Some manufacturers use fine-ground iron oxide to control the total iron content of the glass by compensating for the variation of iron in all the batch ingredients. This is done to control the oxidation–reduction state of the glass and is important for optimizing the heat transmission characteristics of the glass.

Other Glass Compositions

Although E-glass represents the bulk of volume of textile fiberglass produced, other glass compositions are in use in the industry. Table 2 lists some of these alternate compositions and their uses. For some of the glasses listed in Table 2, other batch materials like titanium dioxide and zircon sands are required.

Titanium Dioxide

A 99% pure grade of granular rutile (TiO₂) is often used. Low levels of iron oxide, phosphorus pentoxide, and sulfur trioxide are present as impurities. The particle-size distribution of this material

shows a significant percentage being coarser than 425 μm (40 mesh) with only 1%–2% being finer than 45 μm (325 mesh).

Zircon Flour

Zircon flour, which is used as the source of zirconium dioxide (ZrO₂) in the special glass formulations shown in Table 2, is composed of 66% ZrO₂ and 32% SiO₂ with trace quantities of Fe₂O₃, TiO₂, and Al₂O₃. Hafnium is typically present along with zirconium in the ore body in a 50:1 zirconium to hafnium ratio. Thorium and uranium are also present in concentrations up to several hundred parts per million. Particle-size requirements are similar to those for silica flour, namely 95% or greater being finer than 45 μm (325 mesh).

THE USES OF FIBERGLASS AND MARKETS SERVED

Insulation Fiberglass

Insulation fiberglass is made into many shapes and forms and sold into many markets. The sections that follow describe some of the common applications for insulation fiberglass.

Building Insulation Products

Fiberglass batts, blankets, rolls, and loose fill–blown-in insulation find common application in insulating buildings of all types, from residential homes and light commercial buildings that use wood frame construction to commercial buildings that use metal frame construction. Building insulation is identified and labeled by R-value. “R” stands for resistance to heat flow, with high R-value products having greater insulating power. Commonly available products range in insulating value from R-11 to R-38. Batts and rolls are available unfaced or often with vapor-retarding facings already applied. These facings usually consist of asphalt-coated kraft paper, aluminum foil, or plastic film. The vapor barrier’s purpose is to resist the movement of moisture to cold surfaces where it could condense to liquid water and damage the building. Batts are sold in nominal sizes in lengths ranging from 1,194 mm (47 in.) to 2,438 mm (96 in.) and widths

ranging from 279 mm (11 in.) to 610 mm (24 in.). Rolls come in lengths of 11.94 m (39 ft 2 in.) to 21.49 m (70 ft 6 in.) and in widths of 279 mm (11 in.) to 584 mm (23 in.). A recent development is to encapsulate light-density batts in plastic sheathing to provide an easier handling product that has less associated dust and itch. This type of insulation is installed in exterior and interior wall cavities, ceilings, basements, and crawl spaces. In addition to providing thermal protection, it is also used for its acoustic properties of providing sound control.

Air Handling Systems

Fiberglass duct board, duct wrap, and duct liners are used to insulate air handling systems. Duct board is designed for easy fabrication into rectangular ductwork. In some ducts, the fiberglass board products are part of a system that also consists of coating products and air turning vanes. These smooth interior coatings provide a low resistance to air flow, will not support microbial growth, and resist penetration of incidental water into the fiberglass wool core. Duct liners are designed for lining sheet metal ducts in heating, ventilating, and air-conditioning (HVAC) systems. They provide good thermal insulation and their acoustic properties also dampen sound. Duct wrap is used as thermal insulation for the exterior of HVAC systems where temperature control is required. In many instances, these products meet surface burn-through requirements because of their limited combustibility.

HVAC Systems

Fiberglass blanket and board insulation products find common use in air conditioners, furnaces, and other HVAC equipment. In some cases, the blanket is faced with a smooth, durable, nonwoven mat that is used as a thermal and acoustical control liner in HVAC equipment. In others, acrylic coatings are applied. These insulation products have low air friction, are resilient and flexible, have high tensile strength, and are easy to install. They are incombustible and nonhygroscopic. Some come with acrylic coating formulated with antimicrobial agents to protect against microbial growth. There are requirements for corrosiveness, moisture vapor sorption, fungi resistance, temperature and erosion resistance, odor emissions, surface burn characteristics, thermal conductivity, and sound absorption coefficients.

Pipe Insulation

Fiberglass pipe insulation is made from glass fibers bonded with a thermosetting resin, jacketed with a reinforced vapor retarder facing, and equipped with an adhesive closure system for sealing. It is used to insulate pipe where temperatures range from -20°C (-4°F) to as high as 454°C (850°F). Section lengths can be as long as 1.2 m (4 ft). For some applications, precision V-grooves are machined into the insulation making for a more precise fit. For large diameter shapes such as pipes, tanks, ducts, vessels, and other round and irregular shapes, a high-temperature, semirigid blanket bonded to a flexible facing is used. These products are sold as rolled goods in 0.92-m (3-ft) or 1.22-m (4-ft) widths with thickness up to 102 mm (4 in.).

Acoustics

For acoustical applications, fiberglass board products find wide use in office furniture, office partitions, ceiling panels, and wall panels where high thermal and acoustical efficiency in a minimum space is required. In some applications, these products have a fiberglass mat facing on one or both sides. Requirements for these products include high tensile strength and resiliency; light weight; and resistance to vibration, settling, and shock down. These products are incombustible and will not support microbial growth.

Appliances

Fiberglass board and blanket-type insulation products find common application in household appliances such as ranges, refrigerators, freezers, and water heaters where thermal and acoustical requirements must be met. Certain products are designed specifically for low-temperature applications found in freezers and refrigerators. For application in ovens and ranges, the insulation must be designed to emit minimal smoke and odor. None of these products contribute to or absorb odors, and all pass UL fire hazard classifications.

Aircraft Insulation

Insulation for use in aircraft fuselage wall cavities is made from blankets composed of ultrafine glass fibers. These products must be lightweight and flexible, with superior thermal and acoustical properties and excellent dimensional stability. Where bonded insulation is required, blankets are furnished with water and oil-repellent thermosetting phenolic binders, which also make the products flame resistant and nonpinking. The water repellency is critical for areas where high-altitude moisture condensation occurs. In some areas, contact with oils or oil-based liquids can occur, and providing protection against this type of contact is also necessary. In higher-temperature applications, unbonded insulation is required. The absence of binders and oils eliminates potential contamination from outgassing or binder vaporization. Because of the fine-diameter fibers, these products are ultralightweight and superior in acoustic and thermal performance per unit weight of insulation used. Bulk density of these products may be as low as 9.6 kg per m^3 (0.6 lb per ft^3). Special binderless fiberglass felts are also used to insulate aircraft and jet engines. These felts are intended for continuous exposure to hot face temperatures up to 482°C (900°F). Again, because these products do not contain binder chemicals, there is no outgassing or binder vaporization.

Automotive

Fiberglass insulation is used in molded hoodliners, headliner substrates, dashboard insulators, and other automotive acoustical components. To reduce objectionable dust generated during installation of these parts, glass fibers are bonded with latex binders to encapsulate the intersections of the fibers, allowing them to bend without shattering. These products have excellent dimensional stability and strength, and acoustical and thermal properties. They are also lightweight, flexible and odorless, easy to mold, and they bond well to decorative facings.

Marine Applications

Fiberglass blanket and board products are used for insulating marine products and ship hulls and decks, in shipboard heating and air-conditioning systems, and on drilling rig platforms. Some of these products are characterized by low organic content to improve their performance in combustibility testing. In these applications, key characteristics are high thermal performance, light weight, and low combustibility.

Cryogenics

A fiberglass blanket bonded with melamine resin is used to insulate cryogenic tanks containing liquefied gases such as oxygen, nitrogen, argon, and helium.

Filtration

Fiberglass roll goods are made into bag or pleated filters for industrial and commercial air filtration applications such as ASHRAE (American Society of Heating, Refrigerating, and Air-Conditioning Engineers) high efficiency particulate air (HEPA), and ultralow

penetration air (ULPA) filters for clean rooms, face masks, respirators, vacuum bags, panel filters and filters for HVAC systems, and paint spray booths. They are also used for Food and Drug Administration (FDA) applications. In liquid filtration applications, both cured and uncured roll goods are used in liquid/gas separators, liquid/liquid coalescers, oil and gas coalescing, solids/liquids and solids/gas filter cartridges and filter pads.

Microfibers

Microfibers are glass fibers with diameters ranging from less than 0.5 μm to 2.5 μm . They are used in HEP A and ULPA filters in clean-room applications for many industries, including the manufacture of microchips. Microfibers are also supplied to the lead-acid battery market for use as battery separators in automotive, heavy equipment, and machinery batteries. In some highly specialized applications in the health care industry, microfibers are used for filtering blood particles.

Textile Fiberglass

Textile fiberglass is produced in a variety of forms that are necessary to describe before discussing the markets into which they are sold.

Textile Products

A strand is defined by the diameter of its filaments, its linear weight or tex count (grams per kilometer), the direction of twist, and the number of turns per meter. Single yarn undergoes a single twist operation with between 20 and 40 turns per meter. Plied yarn is made from two or more single yarns twisted together in the opposite direction to the original twist. The yarn is supplied on a cone and can be used directly on industrial process machinery for uses such as weaving, braiding, covering, and so forth. Once it has been transformed by textile processing, it is most often used as a reinforcement or support for various materials such as synthetic resin, bitumen, mica, paper, or adhesive.

Roving

Roving is produced either directly from the bushing by drawing a large number of filaments, or by assembling several strands in parallel, with no twisting. Roving consisting of filaments from 10 to 24 μm in diameter is most often used in linear weights or counts of 600, 1,200, 2,400 and 4,800 tex. Presented as a spool wound on a tube, roving unwinds very easily. The characteristics of roving are stiffness, equal tension of fibers, lubricity, and ease of cutting. Roving can be used in different processes such as weaving, continuous impregnation, or chopping.

Chopped Strands

Basic strands, which are generally cut to lengths from 3 to 12 mm ($1/8$ to $1/2$ in.), have numerous applications. They are used mainly in large series processes to reinforce thermoplastic and thermoset resins and are also used to reinforce plaster, cement, and paper. The characteristics with respect to integrity, flowability, and compatibility will differ depending on the application.

Continuous Filament Mats

Continuous filament mats are felts of continuous filaments distributed in uniform layers as they leave the bushing. They are held together by a binder, and the type and content of the binder depend on the intended application. These mats are particularly well suited to molding between matched molds, and to the production of continuous profiles and circuit boards. They are also used for foam

reinforcement. They are easy to draw and are a simple way to obtain "pre-forms" of the shape of the part to be molded.

Chopped Strand Mats

Chopped strand mats are felts or mats consisting of glass strands chopped to lengths of mostly 50 mm (2 in.) and held together by a binder that is soluble in styrene. The binder content may vary from 3% to 6%, depending on the requirements in terms of processing of the mat and the characteristics of the finished product. Chopped strand mats are particularly suited to contact molding and to continuous molding between layers of film.

Woven Rovings

Woven roving fabrics are made of roving glass strands. The fabrics are manufactured mostly as fabrics with a uniform warp and weft setting but also as unidirectional fabrics and as tapes. They are used for hand lay-up, injection molding, and press molding for the production of laminated glass-reinforced plastics for use in industry, transport, sports, and leisure activities.

Glass Mat

Glass mat is a nonwoven material, composed of uniformly distributed glass strands. These are bound by means of organic additives, mainly thermosetting resins. These form a paper which, after polymerization, is rolled up and packaged ready for use. Glass mat is not susceptible to atmospheric agents or to ultraviolet rays, is supple and traction-resistant, will not rot, and is dimensionally stable. Its porosity makes it easy to impregnate. It also demonstrates good chemical resistance and possesses excellent waterproofing, anticorrosion, and fire protection characteristics. The two processes used to manufacture glass mats—the wet and dry processes—produce different types of paper. Their diverse applications satisfy the technical requirements of a range of sectors such as insulation, automotive, roofing, and construction.

Textile Fiberglass Markets

Markets into which textile fiberglass is sold are described in the following sections.

Transportation

Fiberglass composites are used in a number of applications within the transportation market. These include exterior door panels, radiators and ignition components on passenger vehicles, side panels on light- and heavy-duty trucks, hoods, hatchbacks, roof and truck panels, wing mirrors, rear light units, brake linings, ignition components, and mufflers. The benefits of using composites include greater fuel efficiency, corrosion resistance, low weight and high strength, impact resistance, freedom from rust, and the ability to apply a high-quality finish.

Structural and semistructural parts made of composites have good flexural strength and rigidity. Parts often having a high glass content are front-end panels, flooring, engine blocks, bumper beams, leaf springs, spare wheels and covers, fuel tank supports, inlet manifolds, cooling modules, and oil pans.

Construction

Composite applications in the construction market are numerous. They extend from the exterior walls and the roof to the interior of the home or building. In some cases, glass strands are visible, and in others, the glass is incorporated in a plastic or cement matrix. For exterior applications, composites are used in the following areas:

- Doors and windows
- Gutters, downspouts, and outlets

- Columns, pedestals, domes, and cornices for exterior design
- Paneling, cladding, covering for protection, and insulation panels
- Shingles and other roofing applications
- Translucent flat or corrugated sheets and facing for decorative fascia
- Renovation of fascia using glass-cement composites
- External insulation and coatings of facades where dimensional stability and prevention against cracking are required
- Molds for concrete

Interior applications for composites are also numerous and include

- Gypsum boards and wall partitions
- Composite panels
- Glass-reinforced plaster
- Dry-wall tapes
- Flooring
- Wash basins, showers, sinks, and toilets
- Blinds and shades for decoration and protection from the sun
- Aesthetic coverings for use on walls, partitions, ceilings, and doors
- Decor and furnishings
- Decorative items

Advantages that composites bring to the construction market are dimensional stability, high strength, reduced weight, impact resistance, low flammability, low maintenance, and design flexibility.

Infrastructure

In this market, fiberglass composites have numerous applications:

- In primary structural items, composites are found in pilings, bridge decks, and cable stays.
- In infrastructure restoration, composites are found in column wrapping, pipes, and structural cladding, and are used for in-situ repair of structures.
- In hybrid structural items, composites are combined with conventional materials like wood, steel, or concrete.
- In electric power transmission, composites are used in utility poles, transmission poles, and cross-arm members.
- In highway safety and roadside installations, composites are used in sign supports, guardrails, posts and supports, and noise barriers.
- In seismic-resistant applications, composites are used to repair damaged structures, to upgrade existing structures, and to build new construction that is less prone to earthquake damage.
- In bridge construction, composites provide a high load capacity with low material weight.
- In pavement reinforcing, composites are also used.

Other infrastructure applications are composite reinforcing for concrete products such as dowel bars, reinforcing bars, and post-tensioning and prestressed tendons.

In these applications, composite materials bring a number of benefits, including high strength, reduced weight, corrosion resistance, low maintenance, dimensional stability, low installation costs, and design flexibility. Composites are very durable and will not corrode like steel or rot like wood, so maintenance and replacement costs are reduced.

Corrosion Resistance

Unlike other materials, composites are ideally suited for corrosive environments. Applications in this market include pipes, fume-handling ducts, underground petroleum tanks, sucker rods, flood control, and navigational waterway structures like dam gates and weirs, energy production structures for oil and gas production like offshore platforms, and miscellaneous process equipment.

Recreational

Composites are found in a variety of consumer goods, particularly recreational and sporting goods products. These products include water and snow skis, kayaks, snowboards, golf club shafts, golf carts, fishing rods, and swimming pools. The benefits of using composites for consumer goods include strength, low weight, resilience, flexibility, and corrosion resistance.

Marine

Composite materials are used in a variety of applications in the marine market, including the materials used in the construction, maintenance, repair, and equipping of powerboats, sailboats, and other watercraft. Composites bring myriad benefits to marine applications, including high strength, reduced weight, corrosion resistance, dimensional stability, and design flexibility.

Appliances and Business Equipment

Composites are used in a number of different applications in this market, including gears, pans, housings, and other components for household appliances such as washers, washing-machine drums, dryers, waste disposal units, air conditioners, and humidifiers. Composites are also used in computer terminal housings and in business equipment such as copiers, cash registers, and mailing equipment.

Electrical and Electronics

Composite applications for electrical and electronics markets include light poles, circuit boards, electrical junction boxes, ladder rails, antennas, fuse boxes, lamp housings, street light shells, and switchgear cabinets.

As sheathings used in conjunction with lacquers and coatings, composites are used for covering wires and cables as insulators. The mechanical and electrical characteristics of composites allow very thin coverings to be produced, thereby reducing the volume of electrical equipment.

Glass strand fabrics play an important part in the electronics industry, where they are used to produce copper-plated laminates in printed circuit board manufacturing. The benefits of using composites in these applications include high strength, low weight, dimensional stability, design flexibility, cost performance, and corrosion resistance.

Aerospace and Aircraft

Aerospace and aircraft applications include overhead storage bins, aircraft toilets, and helicopter rotor blades. Benefits from using composites for these applications include cost performance, dimensional stability, and corrosion resistance. Composite materials are light in weight, can withstand heavy loads, and provide excellent resistance to bumps and impact.

FIBERGLASS MARKET TRENDS AND FORECASTS

In a report published by the Freedonia Group (2003), a leading international database business research company, by 2007, the U.S. demand for glass fibers is projected to increase 2% per year to 3.1 billion kg (6.9 billion lb), having a market value of \$6.8 billion.

The segment projected to have strong growth is the fiber-reinforced plastics (FRP) market, where the growth rate is expected to be between 2.5% and 3.0%. The size of this segment is estimated to grow to more than 0.5 billion kg (1 billion lb). Opportunities in FRP will stem from their advantages over competitive materials, where products made from FRP are lighter in weight, are superior in corrosion resistance, and have a favorable cost/performance profile. Building products and motor vehicles will be the leading applications. Good growth is also expected for electrical and electronic markets, which continue to be stimulated by rapid advances in computer and telecommunications technology.

Demand in other reinforcements applications, such as asphalt construction products, mechanical rubber products, paper products, and fabrics is projected to rise 2.3% yearly to 0.6 billion kg (1.3 billion lb). The best prospects are expected in mechanical rubber reinforcement applications, based on usage in a broad range of industrial component applications. Asphalt construction products will continue to account for a large portion of overall demand as a result of above-average growth for laminated shingles, which utilize 30% more glass fiber than standard asphalt shingles. Among nonreinforcement uses, filtration and other smaller markets such as battery separators will provide good opportunities based on rising demand in high-efficiency filtration and other applications.

In the insulation segment, overall demand is forecast to increase 1.7% annually to 1.9 billion kg (4.1 billion lb), with residential construction accounting for approximately 70% of the total. A projected deceleration in residential construction activity will strongly limit growth prospects, but reductions in single-unit conventional housing starts will be somewhat offset by a growing after-market demand, as well as by more intensive use of fiberglass insulation per new housing unit. The best opportunities are anticipated in nonresidential construction because of rebounds in office, commercial, and industrial construction applications.

Flat Glass

Ed McCullah

HISTORY

“Flat glass” is a designation given to glass that was historically produced for windows with the purpose of keeping out wind and rain while letting in light. As processes for producing flat glass improved and evolved, other uses were developed to take advantage of the product’s improved flatness, more uniform thickness, stronger durability, and better optical quality.

The flat glass industry has undergone two technological revolutions in the twentieth century. The first of these, occurring in the period between World War I and World War II, transformed flat glass manufacturing from a batch to a continuous process. This period included the development of several commercially successful sheet glass production techniques, such as the Colburn, Fourcault, and Pittsburgh processes. In addition, plate glass manufacturing was developing to the point that, by the start of World War II, the technology for continuous twin grinding and polishing of the plate ribbon was in commercial use.

The second revolution, which has taken place in the last 50 years, has involved the development of processes for forming flat glass on a substrate of molten tin—the development of float glass technology. The history of float glass (a type of flat glass) actually began in the mid-nineteenth century when Henry Bessemer became the first person to recognize the advantages and filed an early patent (Bessemer 1848). The first U.S. patent describing the manufacture of flat glass by pouring molten glass onto a liquid metal bath and then drawing the bath into an annealing lehr was issued to William Heal in 1902. Further work led to another U.S. patent issued to H.K. Hitchcock in 1905. The Hitchcock patent dealt with the compartmentalization of the tin bath to provide temperature control of the glass ribbon.

The great breakthrough in float glass was made by Pilkington Brothers in the 1950s. Starting from a clear, well-defined objective—to fire-polish rolled glass on a liquid metal substrate and thus avoid the grinding and polishing operations—they were able to develop the first commercially successful process. The development took 7 years of massive effort and expenditure. Its success is a direct result of the vision and pertinacity of the workers involved and to the patience and economic courage of Pilkington Brothers’ management. The problems encountered during these years (until approximately 1962) were primarily of an engineering and chemical nature. It was the solution to these problems that ended the first phase of float glass development. The U.S. patent by Pilkington Brothers was issued in 1965.

Up to now, most activity has centered on the development of techniques for making a float glass ribbon thicker and thinner than the so-called “base/equilibrium” thickness, which is 6 mm. As the process matured, it was capable of displacing plate glass in the mid-1960s and was, by the 1970s, clearly capable of replacing sheet glass as well. The advantages of higher quality, more flexibility, higher production volumes, and economics became very obvious.

FLAT GLASS PRODUCTION

Batching

Batching is the process of unloading, storing, weighing, mixing, and conveying the raw material to the melting furnace. The plant of today is essentially fully automated with some type of computer or controller. Each part of this process must be tightly controlled to minimize cross contamination of raw materials and to achieve accurate weighing and optimum mixing. All processes also include some type of cullet (broken glass) recycling, not only from in-house losses but also from customer-returned product. For lines that use several colorants to produce different colors and products, the storing and controlled recycling of cullet can be extremely critical. Very small amounts of cullet with colorants not accurately compensated for can lead to off-color and out-of-specification product. Although sometimes taken for granted, the batching area is the first step toward a good product. A mistake in this area cannot be corrected later in the process.

The importance of a consistent supply of raw materials cannot be overemphasized. Tight controls, along with monitoring of each raw material for composition, grain size, and impurities, are required. Slight variations can result in major problems. Transportation of the raw materials is just as important. Dedicated railcars and trucks are preferred, but not always available. In situations where other materials are involved, an agreed-upon and documented cleaning procedure may be necessary.

Melting

The float glass furnaces of today, although similar to those of the 1960s, are continually changing. The furnace has been the heart of the process and typically the limiting factor. The driving force for improvement has been the ultimate cost and quality of the final product. The key areas of improvement in the past 40 years have been product quality, volume produced, furnace life, and energy usage. These items are interrelated in that changing one also has a

direct impact on the others. Instrumentation, computers, and modeling, for example, have allowed monitoring and control to drastically improve. Better refractories, materials, construction, and hot-repair techniques have helped increase the life of the furnace (the campaign), to the point that the campaign has increased from 5 years to current targets of 15 years. Improved insulation packages and better combustion control have improved fuel efficiencies. Furnace size increases and design changes have helped in all areas.

Although most U.S. furnaces use natural gas for fuel, a few use oil. Some use oxygen/gas burners for extra melting capacity to increase production and improve quality. There are currently three 100% oxygen/gas-fired float lines. Some electric boost is being used for furnaces that melt high-iron automotive glasses. With the rising energy costs facing the producers today, much work is being done to optimize current technology and to look for new methods and fuels for the future.

Furnaces are normally considered to have three main areas: a melter where the raw materials are melted and liquefied, a refiner to allow gas bubbles to escape, and a working end where the glass is cooled before exiting into the bath. Melting temperatures in excess of 1,600°C are common.

Forming in the Bath

The float bath, which contains >100 t of molten tin, is electrically heated and then purged with a nitrogen-hydrogen mixture. The glass is poured onto molten tin where it “floats” because of the density difference between the glass and the tin. The continuous ribbon of glass moves through the bath where it is controlled with heat and top-roll machines to form a desired thickness and width. The glass is pulled by a system of rollers that conveys the glass through the entire process. Glass enters the bath in the temperature range of 1,050° to 1,200°C and exits at 575° to 625°C. Glass thicknesses from 0.3 mm to 25 mm have been produced. After more than 40 years of use, the float bath still remains the primary method for producing flat glass in high volumes at low cost.

Annealing

Once the ribbon of glass is formed in the bath, it enters the annealing lehr. The lehr has two functions and areas: the permanent and the temporary. The annealing range (550° to 490°C) determines the strength, flatness, and cutting properties that the glass will have at room temperature. This is termed the permanent zone because these properties will remain with the glass unless it is reheated or tempered. Below the annealing range, the glass enters the temporary zone where the goal is to rapidly cool the glass to room temperature for cutting. Once the glass reaches room temperature, the temporary properties are gone and only the permanent remain. Improper cooling rates and too much stress buildup can result in breakage, flatness problems, or cutting problems.

Inspection

Once the ribbon passes through the lehr, it is inspected and out-of-spec defects are marked. Most lines today are using automatic inspection systems that employ lasers or camera systems, or both, for detection. The higher production speeds and requirements for smaller defect detection and identification are continually pushing the limit for the current equipment.

Cutting and Packing

The final step is the cutting and packing of the products. Today's customers require an almost endless number of sizes that range from 130 in. × 230 in. down to 12 in. × 12 in. This has required greater flexibility in the cutting systems and has led to complete computer-

ization. Packing is evolving from a totally manual process to one that uses automatic equipment. Once again, the packing equipment needs the flexibility to pack any number of different sizes.

Environmental Concerns

The impact of changing environmental regulations has not bypassed the glass producer. Like all other manufacturers, the impact has been absorbed into the product cost. In the United States, the major areas of environmental concern are nitrogen oxides (NO_x), sulfur oxides (SO_x), and particulates. The particulates can be controlled in several ways, but the electrostatic precipitator (EP) has proven to be the main method. SO_x can also be controlled inside the EP using a soda ash slurry that is injected into the exhaust stream and collected. NO_x has proven to be more of a problem, and many different methods for its reduction are being practiced throughout the float and other glass industries. Depending on the location of the plant, different levels of NO_x are allowed, and this may dictate the method or practices to be used. Controlling NO_x without damaging the furnace or shortening its life, while maintaining cost controls, has become a tight balance.

Production Locations in North America

Table 1 lists the current operating float glass production lines by company. The impact of the global company influence is evidenced by the fact that the AFG (Asahi Glass) and Pilkington (formerly LOF) companies are both foreign owned.

RAW MATERIALS USED IN PRODUCTION

Base Batch Ingredients

There is no set or standard composition used by all the glass manufacturers, but they typically run in a close range for the major ingredients, especially for clear glass. Table 2 shows a typical base for clear float glass.

Although these are the base ingredients, a typical composition also includes numerous minor elements. Their types and amounts will vary with the location of the mine, quarry, or process, but these minor ingredients are typically potassium (K₂O), titania (TiO₂), alumina (Al₂O₃), zirconia (ZrO₂), manganese (MnO₂), and iron (Fe₂O₃). Today a full analysis of all the ingredients is compiled and input to a computer, which calculates the batch recipe. The processing, sizing, and transportation of these materials are also very important to the glassmaker to ensure no contamination, consistent melting, and reliable delivery. Some contaminants can be disastrous to the producer when they arrive as larger particles that do not have enough time and/or temperature in the process to melt. Two of the most difficult to handle are chromite and alumina.

Additives for Color, Properties, and Forming

For automotive glasses, the composition for many years used a higher level of iron (0.4% to 0.6% Fe₂O₃), which gave a green product. Sometimes a small amount of cobalt was used with the iron to give a green/blue tint. As the automotive industry became more concerned with air conditioning and heat buildup in vehicles, compositions with higher iron levels were used to absorb/reflect more of the solar heat and ultraviolet (UV) radiation. Some compositions used cerium and titania for improved UV protection to prevent fabric fading and protect passengers. With the production of minivans and sport utility vehicles (SUVs) came even more glass usage, which again caused air-conditioning and heat-buildup concerns. Glass manufacturers responded with what has been labeled as “privacy” glass, which is a very dark product that again helps control solar and UV properties. These glasses are made with iron (Fe₂O₃) levels >0.8% up to 1.5% and different combinations and amounts of cobalt, selenium, nickel oxide, titania, cerium, niter, and manganese,

among others. The color can be controlled to produce a green, gray, blue, or bronze product tint using combinations of the colorants and tight control of the furnace redox.

For architectural glasses, mostly gray and bronze products are used, but several blue, blue-green, and green products are also on the market. These use essentially the same colorants as the automotive privacy glasses. Several of the newer products are essentially the automotive products under a different name. Once again, it is control of the solar properties that is critical in the building design in addition to the beautiful colors that can be selected.

Specialty glasses such as a low-iron product are being made for furniture, glass shelving, industrial needs, solar products, and so forth. These glasses sometimes have less than 0.015% iron. They require that the raw materials contain very low levels of iron. Tight furnace control of the redox conditions is needed to maintain the iron at the desired color shade. A more oxidized glass will cause the remaining iron to turn yellow, and this sometimes requires the addition of a small amount of cerium and niter. If a blue shade is

Table 2. Typical base for clear float glass

Oxide	Percentage Range	Source
SiO ₂	71.5–73.2	Silica, silicon dioxide (SiO ₂), silica sand

desired, the furnace is operated under reducing conditions and a small amount of cobalt might be added.

FLOAT GLASS PRODUCTS

Market Breakdown by Section

Although the market end use for glass varies with the introduction of new products, it has remained reasonably stable for several years. The increasing number of cars has been offset by windows (both residential and architectural/commercial) that use multiple panes of glass. The latest numbers from the AFG Marketing Group (2003 data) indicates a breakdown in the sectors as follows:

Automotive	23%
Residential	42%
Architectural	24%
Specialty	11%

Automotive Glass

As designers continue to develop the new looks of today's vehicles, the role of glass has continued to be an integral part of that design. Today's designers are concerned about color, solar heat, UV rays, weight, styling, and security. Each of these items has forced changes to the basic glass product and continues to challenge the producers.

Originally, basic automotive glass was clear. This changed to green tints (achieved with Fe₂O₃) in the 1970s as the desire to increase sun shading became important. As designers began to increase the amount of glass used, the heat buildup in a parked car and the air conditioning required to keep a car cool were added to the list of concerns. The first move was to increase the amount of iron used to darken the green color, which lowers the light and solar transmittance. This approach was limited by a federal standard that requires a minimum of 70% light transmittance in all passenger car glass. For SUVs, mini vans, trucks, and so forth, this law applies to the windshield and the front-door glass only. The concern about UV rays also came to the fore at this time in connection not only with personal health, but also with fabric and dash fading. Glassmakers found that they could optimize the solar and UV protection by controlling furnace redox and/or using small amounts of cerium, titania, or both.

With the success of minivans in the 1980s, SUVs in the 1990s, and passenger-styled trucks recently, the privacy glass wave of products evolved. Light transmissions were reduced to less than 20% in some products to further reduce solar heat and UV rays. This has also allowed color to be more of a choice. Today's designers can use, for example, green, gray, blue, and bronze shades of glass, and engineers can design smaller air-conditioning systems. These glasses have been a real challenge to the producers not only in the melting area, but also in the seemingly continuous color transition that generate tons of off-color product to be recycled.

As the glass composition options became limited by the 70% light transmittance regulation, the use of coatings on the glass and

laminating materials with additives has increased. These have allowed further decreases in solar and UV transmittance while continuing to meet the 70% minimum for light transmittance.

The continuing cycle of concern about fuel mileage has led to the use of thinner glass products in an effort to reduce overall vehicle weight. Although this is not a melting concern, it is a forming problem for the bath. Thinner products normally result in poorer optical properties. The old standard to improve optics is to run slower and produce less, but this leads to higher production costs. Glass less than 1 mm has been used, but problems with fabricating parts, breakage, and road and wind noise, among others, continue to limit the reduction in thickness.

Styling is a designer's dream but often a producer's nightmare. The windshields that lay down seemingly almost horizontal result in increased optical problems. This, combined with thinner glasses, results in very tight control ranges. The large wraparound pieces are very difficult to bend and form without problems. The many bends, numerous holes, and curvy shapes also increase the fabricator's difficulties.

Security is probably the latest item of concern to fabricators. The standard for many years has been laminated windshields and tempered side and back glass. Tempered glass, although tough to break, can be broken, resulting in very quick entry into the vehicle. Several of the high-end cars today are also using a laminated product for side glass. Instead of a single 3.6-mm tempered glass piece, the new units are two pieces of 1.6- to 1.8-mm laminated glass.

Residential/Window Glass

The traditional glass of choice has been and continues to be a clear product. Just as the automotive designers began to be concerned about heat buildup, heat loss, and UV rays, the homeowners have done likewise. Unfortunately, glass cannot be made to control and mitigate these concerns without decreasing the light transmittance, which is totally undesired in this application. The first step was to improve the thermal barrier by the use of insulated glass (IG) units that consist of 2 and sometimes 3 lites of glass, sealed in a unit with an air space separating each lite. These units continue to be refined in design by using different and more efficient construction materials, spacers, and gas filling. The next step was to further control the heat escaping from the house and the solar heat and UV rays entering the house. This has been accomplished with the use of coatings and a group of products termed Low E, which stands for low emissivity. Low E glass is coated with microscopically thin, virtually invisible metal or metallic oxide layers to reduce the U-factor by suppressing the radiative heat flow through the window. Low E coatings can be applied on the float line (pyrolytic) or ofline (sputtered). The coatings differ in their durability—the on-line pyrolytic type is the most durable, which allows it to be exposed to the weather and outside conditions. Because the sputtered products are less durable, they must be glazed inside an IG unit.

The coatings have been further refined to include products that are better in colder climates than in warmer climates. Color control is also a key control for the coatings, as slight variations can change the color from a neutral to a blue or green shade, among others, when viewed in reflection.

In areas where hurricanes and high winds are a risk, some building codes are now requiring that the glass be laminated like a car windshield.

Architectural/Commercial

Color and solar control are at the top of the designer's list of considerations when it comes to large applications. The old standby colors of the past were the gray and bronze tints, but today's palette is almost endless. The base glass can now be of several tints, most

of which have been developed for automotive applications. These can be several shades of green, blue, blue-green, gray, bronze, and so forth. On top of the basic glass, an almost endless list of colors and properties can be added with the coating technology. Both pyrolytic and soft coat products are used for these applications.

Specialty Products

One of the fastest growing areas is the glass for solar collectors. This glass requires the maximum amount of light transmittance possible to obtain peak efficiency. As a result, the iron levels are being reduced to the limit of the available raw materials. Products with <0.015% Fe₂O₃ are being produced. Sometimes small amounts of cerium and niobium are used to control the redox state of the iron to further increase light transmittance.

Other uses of the low-iron products are found in glass for furniture, table tops, shelving, appliances, and lighting fixtures where the traditional dark green edge can be a soft green, a light blue, or almost colorless.

Products for liquid crystal displays, personal computers, touch screens, TVs, computers, and many other electronic and commercial uses are also increasing in volume. These products require very tight quality controls and very thin thicknesses in some applications. Again, coatings are playing a major role in several of these applications.

FUTURE MARKETS AND TRENDS

The forecast for glass sales continues to show a gradual increase in volume in the coming years for the U.S. and North American markets. Unfortunately, the supply and demand in the United States still is on the supply side, resulting in a very competitive commodity market. Glass is a commodity product, worldwide quality is improving, and more imports will most likely be coming to U.S. shores in increasing numbers.

Flat glass producers appear to be following the same path as other manufacturers because the majority of the world's new production facilities are being built in the Far East, particularly in China. China, which is undergoing the largest expansion in the world today, is and will continue to be the biggest concern for the industry. With today's float plant cost pushing \$100 million for a basic plant and glass prices still very soft, the price of labor and energy are key variables.

Technology and productivity improvements have kept the U.S. manufacturers competitive for a long time. This trend must continue. Other areas that must continue to grow are the value-added and specialty products, many of which involve coatings. These niches allow for increased profits only until the technology spreads and others enter the market. At that time, a profitable value-added product becomes a commodity.

Specialty Glass

George H. Edwards, Victor O. Aume

INTRODUCTION

Specialty glasses include that very broad range of glass types, compositions, and end uses that are not flat (window) glass, container glass, or fiberglass. In earlier texts this broad group was sometimes referred to as “pressed and blown ware,” but this definition is not completely satisfactory because it is not specific in terms of composition, nor is it inclusive in capturing the process of forming the product. The U.S. Department of Commerce has published glass-production data that includes fiberglass with the specialty glass data, which clouds the subject somewhat.

Examples of specialty glasses include lighting products (incandescent bulbs and fluorescent tubes), laboratory ware, cathode-ray tubes (CRTs) for television and computer monitors, liquid crystal display flat glass, optical and ophthalmic glasses, glass-ceramic cooking and table ware, soda-lime and borosilicate tableware, and lead crystal and other art glasses including color sticks. Fused silica is a glassy form of silicon dioxide (SiO_2) and is sometimes included in the group, although it is not formed by normal glass-making processes. Optical fiberglass, produced by the flame pyrolysis of silicon compounds, is not considered in this chapter.

The complexity of the subject is reflected in the fact that at one time a leading specialty glassmaker listed nearly 1,000 glass compositions used to manufacture about 60,000 different products (Edwards and Copley 1977). More than 20 different industrial minerals are consumed in the glass industry (O'Driscoll 1990), and the number of specialty chemicals consumed is even greater. Indeed, the dividing line between minerals and specialty chemicals can become blurred as the specialty glassmaker places increasingly stringent demands on the raw material producer by requiring minerals to be more highly processed. At that point it becomes difficult to say whether they have lost their original mineralogical identity and become refined chemicals.

Many specialty glass products, such as tableware and float glass (window glass produced by floating molten glass on a pool of molten tin), use glass formulations which, although specific to the end use, are similar to the great bulk of container glass in that they are soda-lime glasses, formulated with SiO_2 , soda (NaO), calcia (CaO), and small amounts of alumina (Al_2O_3) and perhaps magnesia (MgO) as a stabilizer.

This chapter gives a brief overview of selected specialty glasses and their manufacturing processes but focuses more on some of the industrial minerals used in their production. For greater

detail on glass-manufacturing techniques, consult *The Handbook of Glass Manufacture* by F.V. Tooley (1984).

The glass industry as a whole refers to the oxide when discussing the composition of a mineral or chemical, and this convention is used here, referring to, for example, the potassium content of a feldspar in the form of K_2O , or potash, rather than as the element potassium. This convention is useful for the glassmaker in that most glasses are described by their content of glass formers (SiO_2 , boron oxide [B_2O_3], etc.), intermediates (Al_2O_3 , titania [TiO_2], etc.), and modifiers (MgO , lithia [Li_2O], CaO , etc.), and such an expression is used to calculate the oxide contribution of any given raw material in the batch to the desired oxide composition of the final glass. This in turn facilitates the calculation of the batch composition needed in producing the glass, because in general, glassmaking is a continuous process for which the raw materials are prepared discontinuously in discrete batches, then added to the continuous melting and forming stages.

SPECIALTY GLASS PROCESSES

Lighting

Lighting products such as lamp envelopes (light bulbs) are made from a variety of glass types, including borosilicate, soda lime, and aluminosilicate, although this list is not exhaustive. The processes used in manufacturing these lamp envelopes can be generalized into two categories: (1) lamp blanks (preliminary shapes from which finished articles are made) formed directly in some type of blowing process (such as the ribbon machine); or (2) lamp blanks formed by the lampworking of previously manufactured glass tubing. Glass quality requirements vary among the different applications but are most critical for halogen-type bulbs because of the high operating temperature of the lamp.

Vello, downdraw, and Danner forming processes are used to manufacture tubing (Tooley 1984). Historically, the Danner process was preferred until the Vello process, which greatly increased production rates, was developed. The Danner process is still in use in many developing countries, and for a very few selected products requiring particular dimensional characteristics. The Danner process is a much simpler process than the Vello but is limited by the gravitational flow of the viscous glass, and the stability of that flow down the forming mandrel to provide dimensional control. The Vello process could be thought of as a pultrusion process, where the glass is literally pulled through an annular opening by

the cutting machine at the cold end of the process. The downdraw process differs from the Vello primarily in scale and size of products, ranging upward from roughly an outside diameter (OD) of 51.0 mm (2.0 in.). It is also characterized by being a completely vertical process, whereas Danner and Vello are horizontal.

The variety of sizes produced range from less than 6.0 mm (0.25 in.) OD to as much as 305 mm (12 in.) OD for a downdraw operation, with a variety of possible wall thicknesses. Probably the largest application is for soda-lime fluorescent tubing.

Amid the variety of blowing processes, the ribbon machine for standard light bulbs is the best known. The ribbon machine is capable of making a variety of bulb blank sizes, up to larger specialty bulbs for x-ray tubes and stadium lighting, for example. A stream of glass is formed into a relatively thin ribbon and pulled across the top of a bank of molds. The glass is pressed into the top of each mold and blown out into a bulb. The finished bulb is cracked off the ribbon, and the majority of the ribbon is returned for recycling. Larger bulbs can also be made on gob-and-blow machines, where a small gob of glass is extruded from an orifice, cut and pressed into a patty, and then sagged and blown into a rotating mold. This latter process produces blanks without mold seams because the mold rotates around the glass piece, cushioned by a film of steam.

In developing countries, many such lighting products are produced by hand.

Glass quality requirements for lighting applications can be challenging because the products are relatively thin-walled, leaving no room for inclusions that might be tolerated in thicker ware, such as a bottle. For process stability in high-speed manufacturing processes, a constant and stable viscosity is required, implying that the glass composition must be very stable and also requiring tight control of raw material assays and thorough mixing.

Laboratory Ware and Pharmaceutical Glass

Glasses produced for this industry segment are nearly all borosilicates of one type or another, which have the highest chemical durabilities of common glass compositions.

The durability and inertness is a result of the composition, which is more than 80% silica in the case of heat-resistant glass, with the remainder being boron, soda, and alumina. The resulting low coefficient of thermal expansion also makes this hard borosilicate especially useful in the laboratory where it can withstand direct heating without suffering thermal shock damage. The high amount of silica in the composition also makes this glass relatively difficult to melt, and so the selection of the particle-size distribution of the silica sand used is the most critical element of the raw materials portfolio. Many melting studies have been performed in an attempt to understand the melting dynamics of any particular sand, and although no definitive conclusion has been reached, sands for borosilicate glass are generally finer than those used for other applications. More subtle differences, such as whether the sand source is a rounded beach grain, or a crushed, angular, fractured grain, will also affect the melting process.

The basic forming processes for laboratory ware are similar to those for lighting, with tubing and blownware being the primary manufacturing products. From these basic components, a great variety of products are produced through secondary manufacturing, based on the lampworking process—reheating, shaping, and connecting previously made components. A small sampling of products would include petcocks, distillation and condensation apparatus, reaction vessels, and transfer piping. Nearly every research university with any reasonable interest in chemistry will

have a lampworking department (or at least an expert individual) to custom fabricate the desired process glassware.

The glasses for pharmaceutical applications retain most of the chemical durability attributes of the heat-resistant glass but do so with much less silica in the composition, which makes the glass a bit easier to melt and manufacture. These compositions will also contain varying amounts of potash and calcia, and likely higher amounts of alumina, soda, and boron. They also have the distinction of being produced in an amber color, for ultraviolet (UV) light protection of the contents. Although easier to melt because of lesser amounts of silica, their quality is difficult to maintain because of sensitivity to the oxidation state of the glass, a function of trace residual organics in the raw materials interacting with the melting process. This can affect not only the glass color but also the number of small gas bubbles retained in the melt. Pharmaceutical glass is most often produced as a glass tube initially, with a secondary product forming into an ampoule.

Cathode-Ray Tubes

CRTs, such as television tubes and computer monitors, were developed in the 1930s and 1940s and became a major manufacturing activity in the 1950s and 1960s in North America. The advent of color television in the 1950s required further improvements in the glass compositions, and larger tube sizes pushed the limits of pressing capability.

The composition of the faceplate (panel) glass is based on the need for x-ray absorption to protect the viewer from the radiation produced within the tube when the electron beam is generated to excite the fluorescent coating on the inside surface of the optical-quality faceplate. The glass composition has generally been high in the heavy alkaline earth components and with a small amount of lead to provide the x-ray absorption. With the advent of computer monitors and their problem with x-ray browning (burned-in ghost images), the composition evolved once more to exclude lead and add zirconia (ZrO_2) instead. The funnel glass (so named for its shape) continues to be a high-lead composition, as browning is of no consequence there. The neck tubing for the electron beam source is also high in lead.

Pressing is the most common process for manufacturing panel and funnel glass. A large, precious-metal-clad or refractory gobber is used at the delivery end of the process to extrude the desired quantity of glass (the gob) through an orifice. The gob is then cut, falls into a mold, and is pressed to the desired shape. Once cool enough (a limiting factor because of the relatively high thickness of the panel glass), the glass has a variety of metal components imbedded. It is then annealed and made ready for tube production, which involves applying phosphors; installing various metal components; and welding together the glass parts of the tube, followed by evacuation and sealing.

Because of the stringent quality requirements for the panel glass and the large amount of glass required to produce a panel (in excess of 45 kg [100 lb] each for large specialty tubes), a great deal of effort has been expended to study melting characteristics of various raw materials, working toward the goal of defect-free glass. The high amount of fluxes and modifiers in the composition means that melting (e.g., sand grain dissolution) is not necessarily the primary concern. Instead, residual bubbles, cord (glass inhomogeneities), and refractory dissolution and interactions are the critical criteria for successful production.

The production of CRTs has been, until recently, a premier activity of any glassmaker. In North America and Western Europe, however, the last few years have been extraordinarily difficult for

the CRT glass producer. Significant capacity increases, as well as efficiency improvements, have been implemented in Asia. Economically, only the top-of-the-line products can be manufactured profitably in the developed countries, but as technical and manufacturing capabilities continue their rapid progression in Asia, it is expected that more of these products will be moved there as well. It is not very likely that any primary glass manufacturing will remain in North America by 2010, and the pressures will be very similar in Western Europe.

In any case, the rapidly increasing popularity of flat-screen displays for televisions and computers means that these sheet-glass displays will likely replace the CRT in most applications within a few years.

Liquid Crystal Display Glass

The popularity of thin, flat displays for computer monitors and home entertainment has driven recent rapid growth in this segment of the specialty glass industry, although development has been under way for at least 30 years. The basic forming technology was developed 30–40 years ago with the intention of producing window and automotive glass by a smaller scale alternative to the float glass process.

Although tonnage produced is small, these products are highly profitable for their producers and have evolved into important and proprietary businesses. Assuming that product costs follow the decay curve seen in most newly developed electronic items, flat display panels are expected to replace the CRT as the preferred product for television sets and computer monitors within a few years' time.

The glass material used for these flat-panel displays is unusual in that soda and potash are contaminants to the ensuing semiconductor application and must be controlled to absolutely minimum levels. Often trace levels of alkalis in the raw materials are sources of serious product performance problems for the glass. In addition, the variabilities of the contaminants and material assay cause major instabilities in the melting process.

Because of the semiconductor application requirements, the composition has an extremely high softening point, requiring melting temperatures that exceed 1,700°C (3,092°F) and special materials in the construction of the melting furnaces and glass-handling equipment. Primary melting is powered by gas/oxygen combustion in combination with joule heating. The glass is refined, often in a vacuum-fining process, before proceeding through a platinum-clad mixing, conditioning, and stirring section.

One major producer's forming process consists of a trough that allows glass to overflow both sides and flow down to rejoin below the trough to form a vertical sheet with two optically perfect air-contact surfaces. A sheet is produced up to 2 m (6.6 ft) in width, and as thin as 0.7 mm (0.03 in.) at the current state of the technology. It is then inspected and graded for quality and allocated to its optimum utilization, depending on its quality grade. All processes after the forming pipe are in tightly controlled, clean-room environments.

Optical and Ophthalmic Glass

Optical glasses are extremely specialized, low-volume products. Raw material purity and stability requirements are demanding, often pushing the limits of suppliers' processes and approaching specialty chemical specifications. Because nearly perfect homogeneity is necessary for optical transparency and image formation, glass/refractory contact is often minimized through the extensive use of precious metals, at least in the conditioning and stirring sections of the process. Very precise control of the refractive index is also key to producing these materials.

Ophthalmic glasses are nearly as demanding in terms of quality and purity requirements and often employ similar melting technologies, including precious metals and intense stirring. One of the key product criteria, refractive index control, is a direct result of stable raw material assays. Photosensitive ophthalmic glasses have been produced that include precipitated silver halide crystals that react to ambient UV light levels and, therefore, adjust their degree of tint. Production of these glasses has been eroded by the advent of plastic lenses with similar performance and, undoubtedly, the increased popularity of contact lenses and corrective surgery.

Glass Ceramics

Glass ceramics is an interesting family of materials that are melted and formed as glasses and then, through subsequent heat treatment, grow crystalline phases to take on many attributes of ceramics. They are extremely resistant to thermal shock and have very high mechanical strength. Many of the compositions that have been manufactured have been based on lithia compound crystallization, which has historically made this segment one of the larger consumers of lithia minerals.

Although there are a variety of technical and scientific applications of this type of material, the best-known applications are bakeware and stove-top consumer products. The manufacture of these products has decreased greatly in recent years, and it is not clear whether any are still manufactured in the United States. A few products have been replaced by a variety of traditional ceramic materials. Currently, stove-top surfaces and woodstove windows are still produced from glass ceramics and take great advantage of the thermal shock resistance of this family of materials. Overall production is certainly well below historical levels and likely to continue at that reduced level.

Soda-Lime Table and Cookware

Consumer products cover a broad spectrum of products and glass compositions as well. Soda lime, borosilicate, fluorine opal, laminated glass, and glass ceramic materials have all been used to make products such as measuring cups, bakeware, dishes, and mixing bowls. Primary forming is typically done by pressing, and decorating can be a multistep silkscreen printing process using ceramic-based inks that are then fired onto the ware. Melting furnaces for these products are typical of other glass operations for large-volume commodity glass manufacturing, although the production of opal glasses carries the burden of managing fluorine emissions. For this reason, cold-top melters are so metimes used, greatly reducing emissions and assisting in fluorine retention.

Because the consumer does not have strict technical requirements for the glass material, this has been a field where "look-alike" products have often been applied successfully to produce ware at reduced cost. As one example, instead of making a product from the more expensive and more difficult-to-melt borosilicate composition, some producers have manufactured products from soda lime and then heat-treated the products to result in the improved strength and thermal shock resistance that approaches the performance of borosilicate products. Similarly, some glass ceramic and opal products have been replaced with traditional ceramic bodies, using glazes chosen to mimic the surface quality of the original glassware.

As if recycling glass were not challenging enough, it is further complicated by the mixture of products and materials found within the broad field of consumer products and by variations among producers. Glass ceramics and pottery, if mixed with cullet in postconsumer recycling operations, do not melt well when introduced into the glass furnace.

Art Glass

Because there are few specific technical requirements for this class of applications, the glass compositions vary according to producers and their company traditions and practices, including high lead and soda-lime compositions. Individual studio producers often use one of several standardized glass compositions from the soda-lime family, commercially available in cullet form and as premixed batch.

Lampworking applications tend to be separated into two general families: soda lime and borosilicate. Within any given application, however, there are technical requirements for colorant compatibility and proper annealing.

Larger producers are more likely to employ continuous melters, which require either 2 or 3 daily production shifts, 7 days per week, to support the melting volume and produce consistently reliable quality. Smaller producers are more likely to use pot melters, which offer the advantages of limited production rates (1 shift per day, 1 or more production days per week), while still producing good quality ware. Typically, because this type of ware is produced by hand blowing and forming, the character of these businesses is dominated by the atmosphere of an artisan's workshop, not necessarily a technologically sophisticated industrial approach.

Lead glass, commonly referred to as lead crystal, can range from 22%–30% lead oxide and is the preferred material where its high index of refraction is required to improve the sparkle of the resulting products. The high density of the resulting glass also contributes to the distinctive chime when lead crystal glasses are tapped. Color quality is of utmost importance to these applications, so the concentration of coloring oxides present in the raw materials must be minimized. Some producers will also add decolorizers to produce a neutral grayed color to mask the presence of iron oxide (and other coloring oxides) instead of or in addition to minimizing the iron oxide in the raw materials, most notably from the silica and lead oxide sources. A few producers have investigated melting lead-free compositions, instead using other heavy metal oxides, such as silver and barium, to provide the high refractive index and density.

Soda-lime glass is probably the most commonly used composition in the art glass field; it is the most readily available and has the fewest environmental ramifications. Some colors are easier to produce with soda lime, particularly those requiring reducing conditions, which would precipitate metallic lead within the glass or on its surface. A huge variety of "color sticks" are available to support soda-lime production, and often the producers melt only one or two colors (e.g., clear and opal), and achieve all other coloration with these highly concentrated colorants.

INDIVIDUAL INDUSTRIAL MINERALS AND CHEMICALS

The following sections give an overview of individual industrial minerals and chemicals as used in the glass industry (Harben 2002), with some details of the specific requirements of the specialty glass industry.

Most of the raw materials used in specialty glasses are essentially the same as those used in the larger volume commodity glasses, but with special conditions to fit special requirements. Generally the special conditions involve the level of purity or freedom from contamination of various kinds, but may also include the physical form of the raw material. In many cases the specialty glass in question may have purity requirements that prohibit the use of minerals, no matter how highly refined. An example of this might be the use of strontium carbonate rather than celestite in the production of CRT glasses because the formulation and manufacturing process of these glasses is intolerant of sulfur.

Alumina

The majority of glasses used for large-volume commodity applications, such as containers and windows, contain a small amount of aluminum oxide to enhance mechanical and chemical durability. Generally these glasses, and many specialty glasses as well, derive their alumina from one of the various forms of feldspar. Others, however, must be largely free of one or more of the normal constituents of feldspars, such as soda, requiring some form of alumina or alumina hydrate. The ore mineral bauxite is rarely if ever used as an alumina source in glass because of impurities, but can be used in glass after it is refined into alumina.

Glass ceramics, usually produced to exploit their low coefficient of thermal expansion, cannot contain much soda, so they must get their alumina content from special calcined aluminas. Liquid crystal display (LCD) flat sheet-glass production requires a soda content below 20 ppm to meet the semiconductor application requirements.

Alumina is produced as one step in the Bayer process of reducing the bauxite ore to aluminum metal. The Bayer process involves digesting bauxite in a caustic soda solution at elevated temperatures. The alumina trihydrate produced in this way is electrolytically reduced to aluminum metal via the Hall-Héroult process, or is further processed for use in various industries, including ceramics and glass.

Depending on the purity demands, several alumina products are used in specialty glasses, including calcined alumina produced by firing Bayer-process alumina trihydrate, low-sodium alumina, and high- to ultra-high-purity alumina.

Barium Carbonate

Barium carbonate (BaCO_3) is produced from the mineral barite by high-temperature reduction of the barium sulfate in the presence of sodium carbonate.

Barium carbonate finds significant use in CRTs where the large nuclear cross-section of barium is useful in blocking the x-rays produced by the electron beam impinging on metals within the tube. The baria also serves as a flux and stabilizer.

Baria also increases the index of refraction of the glass, giving decorative glassware greater brilliance. Pure grades of barium carbonate are used to make optical glass, and also to increase the index of refraction. Barium carbonate is also used in LCD glasses.

Boron Minerals and Compounds

Borates—minerals containing B_2O_3 —are relatively rare in nature. The borate minerals used in glass manufacture are restricted to desert regions that are also actively volcanic and where lakes have been present to dissolve the soluble borates before evaporation and deposition. Their high solubility means that borate deposits do not survive for long on the surface; they are readily washed away when the climate turns wetter.

The most commonly used borate minerals and chemicals are tincal ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$), anhydrous borax ($\text{Na}_2\text{B}_4\text{O}_7$), sodium pentaborate ($\text{Na}_2\text{O} \cdot 5\text{B}_2\text{O}_3 \cdot 10\text{H}_2\text{O}$), colemanite ($\text{Ca}_2\text{B}_6\text{O}_{11} \cdot 5\text{H}_2\text{O}$), ulexite ($\text{NaCaB}_5\text{O}_9 \cdot 8\text{H}_2\text{O}$), and boric acid (H_3BO_3).

Even though detergent and fire retardant uses consume significant amounts of borates, glass is by far the largest consumer of these minerals. B_2O_3 contributes a number of desirable attributes to the glass, including reducing the coefficient of thermal expansion, chemical and mechanical durability, easier melting (it is a powerful flux), and increasing the index of refraction.

The form selected for use depends on the composition of the glass. Formulations that include sodium and calcium can use the

lower cost ulexite, but glasses that can tolerate no alkalis or alkaline earths must use boric acid, or even anhydrous boric acid, a glassy product made by melting boric acid to drive off the water, leaving only B_2O_3 .

Glass articles produced with borate minerals and chemicals include cookware, laboratory ware, vessels for the chemical industry, laboratory glassware, and LCDs (Harben 2002).

Borate minerals find major applications in the fiberglass industry, which is covered in a separate chapter.

Calcium Carbonate, Limestone, and Dolomites

By far the largest use of calcium and magnesium minerals in the glass industry is as limestone in soda-lime container glass. Although a reasonable standard of purity and consistency is required for container applications, the dominant characteristic controlling the glassmaker's choice of limestone is price, and because transportation is a major part of the delivered price, most limestones are mined close to where they are consumed.

Carbonate rocks and minerals comprise a wide and varied range of geological circumstances. Included in this group are limestone, chalk, marble, carbonatite, vein calcite, aragonite, sand, and others.

The use of the calcium and magnesium carbonates in the specialty glass field is governed by the requirements of the individual glass compositions, which need to be free of specific contaminants.

Special limitations placed on the calcium carbonate used by the specialty glassmaker may include iron oxide (Fe_2O_3), chlorides, and sulfates. The restrictions may be so tight that the glassmaker will resort to precipitated calcium carbonate, even reagent grade, for limited usage. Few natural calcium carbonate sources, such as limestone or vein calcite, will routinely yield products with Fe_2O_3 of less than 0.05% and this level of iron may be too high for some optical applications. The nature of the glass being made will also dictate whether dolomite or calcite is used, as some of the glasses are not tolerant of significant amounts of MgO.

In any case the use of calcium carbonate rocks and minerals in glass is a very small percentage of the total worldwide consumption of these materials when compared to the huge tonnages consumed in aggregate production and the making of portland and other cements. Ground calcium carbonate, if sufficiently high in whiteness, is used in papermaking, as fillers in plastics and coatings, and in other industrial uses.

Cerium and Other Rare Earths

Along with cerium, some of the other rare earths include elements in the lanthanide series, including lanthanum, praseodymium, erbium, and neodymium. Together or individually, these elements are used to control index of refraction, to reduce optical dispersion, and to introduce various colors. They are also used as oxide coatings on the surface of optics to control reflection properties (Tooley 1984).

Rare earth is quite a misnomer, as the mineral sources of these elements are fairly common in the earth's crust. Overall, these elements are more common than silver, and cerium and lanthanum are more common than lead (Harben 2002). Two minerals, bastnaesite and monazite, serve as the ore sources for most of the rare earths, including cerium and lanthanum. These minerals occur in carbonatite bodies, which are a rare class of igneous rocks consisting mainly of carbonates and phosphates. Carbonatites in China, Russia, and the United States supply the majority of rare earth minerals.

Cerium oxide (CeO) is used as a polish in optical and other glass production. It serves a dual use in the production of CRTs, because it is used both as an ingredient in the faceplate glass and as a polish in the finishing of the ware. Cerium oxide can also be used to

decolorize glass by modifying the valence state of the iron contained in the glass.

Erbium imparts a distinctive pink color to glass.

Other rare earths, particularly yttrium and europium along with cerium, are used in the "phosphors" which fluoresce to produce the colored image on the screen of the CRT when struck by electrons from the electron gun.

Uses of rare earths other than in glass include petroleum-cracking catalysts, specialty ceramics, electronics, and minor medical applications.

Coloring Oxides

One of the most useful characteristics of glass is that it can be colored many different shades and intensities, indeed over the entire visible spectrum. This attribute is used in industrial and technical applications but is of particular value in consumer ware and art glass. The "coloring oxides" include cadmium, chromium, cobalt, cerium, copper, gold, iron, manganese, selenium, nickel, neodymium, and uranium. Sulfur is used in combination with iron to impart the familiar color to brown beer bottles.

Cadmium is introduced as the sulfide (along with some selenium) to produce a ruby red color, or without the selenium to produce a strong yellow. This application has been of considerable commercial importance in turn-signal lamps for automobiles.

Chromium imparts the bright green to many container glasses such as some beer bottles. The element is produced as the mineral chromite, often used directly in the metallurgical trade. Chromite itself tends to be highly insoluble in most glasses, and for this reason chromium is usually batched as the potassium dichromate, $K_2Cr_2O_7$. Chromic oxide is also used in some specialty situations where alkalis are not tolerated.

Cobalt is an extremely powerful coloring agent, just a few fractions of a percent yielding the familiar deep blue seen in much container ware and tableware. The principle use of cobalt other than as a colorant in glass and glazes is as a hardening alloy in steel. Most cobalt is a by-product of nickel mining.

Copper, usually added as one of the oxides, imparts a blue-green color to an oxidized glass. Under reducing conditions, it can produce a red coloration.

Iron will color oxidized glasses green, while under reducing conditions it produces a gray or brown tint. Magnetite is utilized for glasses needing reduced iron, as arsenic derite ($FeCO_3$) or ferrous oxalate (FeC_2O_4). In most glass raw materials, iron is regarded as one of the major contaminants, and most producers of sand, limestone, feldspar, and similar raw materials strive to produce the lowest iron products possible. If the glassmaker wishes an iron color, the glassmaker prefers to add the iron during the glassmaking process. Silica sands for specialty art and optical glass must have Fe_2O_3 contents less than a few parts per million. Pure and carefully sized Fe_2O_3 , termed rouge, is employed as a fine polishing compound in some glass operations.

Manganese is usually employed as the dioxide, MnO_2 . The naturally occurring manganese dioxide mineral pyrolusite is used unless extreme levels of purity are required, in which case purified manganese dioxide or potassium permanganate ($KMnO_4$) are used. Manganese can impart a lavender color to the glass, or in small quantities can be used to counteract the coloration imparted by iron, and thus serve as a decolorizer.

Neodymium, praseodymium, and other rare earths are sometimes employed as coloring oxides. Neodymium and praseodymium often occur together, and can be used in the oxide or carbonate form to produce a purple color. Like manganese, this combination can be used as a decolorizer. When used by itself,

praseodymium yields a green color. There are many specific and small applications for other rare earths where special colors are required in optical or other applications.

Nickel imparts violet hues to glasses and is sometimes used in the oxide form to decolor lead glasses. Nickel is also used to produce CRT faceplate glass, in conjunction with lesser amounts of cobalt and chromium, to produce the desired neutral gray color.

Selenium is used in elemental form as a metal powder. Selenium is widely used as a decolorizer to counteract contamination with iron. In larger amounts and with cadmium it is used to produce a ruby red. Selenium is largely a by-product of the smelting of copper ores.

Uranium has been used in various chemical forms to impart a distinctive green color with fluorescent effects. This color is sometimes seen in antique glassware, but uranium glasses have only limited production today because of industrial hygiene considerations relative to handling of the uranium compounds.

Feldspar and Nepheline Syenite

The term feldspar as used in industry covers a wide range of minerals and rocks, and usually includes nepheline syenite, a plite, and feldspathic sands, all of which are used in various glass applications as sources of alumina, and to a lesser degree of potash, soda, and silica. These are alkali-aluminosilicates containing a range of sodium, potassium, and calcium in a solid solution series (Harben 2002).

Potassium feldspars include microcline and orthoclase, both $KAlSi_3O_8$ in the pure state. Plagioclase feldspars are a series with sodium-rich and calcium-rich end members. Calcium-bearing feldspars include bytownite, labradorite, and anorthite, the last being a calcium aluminosilicate.

Most commercial feldspar deposits are mixtures of feldspars or contain feldspars intermediate between the pure end members. The terminology of the feldspar trade is not always clear, but if potash predominates over soda, usually in the amount of 10% or greater, the feldspar is called a potash feldspar, whereas a soda feldspar will have soda predominating, usually at the level of 7% or more soda.

Feldspars are very common minerals, constituting some 60% of the crust of the earth. They frequently occur in various types of igneous rocks, but feldspars weather easily to clay and soluble alkali carbonates. For this reason commercial deposits of feldspars are usually restricted to mountain regions where masses of relatively fresh, unweathered or partially weathered feldspar-containing rocks are accessible.

Rapid erosion of granitic areas may produce unconsolidated sands enriched in grains of feldspars that have not yet chemically weathered, and these feldspathic sands are exploited for glassmaking in several places, particularly in California, Italy, and Spain.

Nepheline syenite is an igneous rock similar to granite in some aspects but undersaturated in silica, the result being that it does not contain quartz but does contain a silica-deficient feldspathoid called nepheline with the composition $(Na, K)AlSi_3O_4$. This relative enrichment in Al_2O_3 relative to the alkalis and silica makes nepheline syenite of interest to the glassmaker as a source of alumina. Nepheline syenite is produced in a few localities, notably Brazil, Canada, and Norway.

The majority of feldspar and related materials is consumed by the glass industry (Bolger 1995). Specialty glassmakers use these sources of alumina to the greatest extent possible, always considering the levels of purity required. CRT glass production has traditionally been a major consumer of potash feldspar but has used the relatively high-potash nepheline syenite from Blue Mountain, Ontario, in recent years.

The various feldspathic materials compete among themselves for market share, and often the cost of transportation is the deciding factor, questions of chemical composition and purity aside.

Residual organics from the froth flotation process (or other processing) used to beneficiate feldspars can cause problems in specialty glass production in that they can change the oxidation state of the glass. This in turn may result in a color change by varying the amounts of iron in the +2 and +3 valence states. In some borosilicate glasses (neutral borosilicates in particular), this variability in oxidation state can cause bubble defects in the ware produced. Stabilization and control of the amount of residual organics may help some glass producers.

Fluorspar

The only significant commercial source of fluorine is the mineral fluorite (CaF_2), known industrially as fluorspar. Other fluorine minerals include cryolite (Na_3AlF_6), sellaite (MgF_2), bastnasite (a complex rare earth carbonate with fluorine), and fluorapatite (a calcium phosphate with carbonate and fluorine). The great majority of fluorspar production goes to the manufacture of hydrofluoric acid and other fluorine chemicals.

Fluorspar is used in glassmaking as a flux and to produce a white opalescence.

In some specialty glasses, sodium fluorosilicate (Na_2SiF_6), called "sodium silico fluoride" by glassmakers, is used to produce the opalescence.

Fluorine is volatile, and much of the fluorine introduced to the glass in the batch is lost to volatilization, usually into the combustion gases. This requires treatment of the effluent gases, often by wet scrubbing, or an alternative melting process such as a cold-crown furnace. This added cost has resulted in a reduction of the use of fluorine in glassmaking over the past several years.

Lead

Lead compounds, usually oxides, have long been used in glassware because they produce a high index of refraction, which gives the ware an attractive brilliance and sparkle. Lead is usually added as litharge (PbO) or red lead (Pb_3O_4), which are formed by high-temperature roasting of lead metal, and not directly from the lead sulfide mineral galena.

Red lead and litharge are dusty, and present a significant industrial hygiene hazard in handling and batching. To counter this problem, lead producers developed lead silicates, with about 25% SiO_2 , which are safer to handle. Nevertheless, the melting process volatilizes a significant amount of lead, and the use of lead in many large-volume specialty glasses such as CRTs, where it serves to block the transmission of x-rays, has declined significantly in recent years. Lead continues to be used for x-ray protection in the neck and funnel glasses of CRTs, but its use in the faceplate of the tube has been essentially discontinued because of the tendency of lead-containing glasses to turn brown after prolonged exposure to x-rays.

Lead continues to find use in small-volume art crystal and optical glasses.

Lithium

Lithium, the lightest of the alkali metals, has traditionally been produced from pegmatites as the silicate minerals spodumene, petalite, and lepidolite. During the 1990s, the bulk of production shifted from spodumene mined in North America to lithium carbonate produced from desert dry lake brines in Chile. Some dry lake brine production has existed in the United States and China for several years. Australia, Canada, and Zimbabwe continue to produce silicate-sourced lithium, but at reduced volumes compared to historical levels.

In the Sal de Atacama of Chile, shallow-well brines are pumped to large evaporating ponds where they are concentrated by solar evaporation. The resulting lithium chloride-enriched liquor is reacted with soda ash to precipitate the lithium carbonate.

Lithium finds use in many specialty glasses at small fractional percentage additions—usually less than 0.2% by weight. It is a powerful flux and can be used to reduce the melting temperature and viscosity of the glass, or to increase furnace throughput. The reduced viscosity has been shown to increase the rate of fining of the liquid glass (fining is the process by which bubbles are removed from the freshly melted glass).

Lithium can be used as a flux in place of fluorspar in CRT glass.

A major consumption of lithium has been glass ceramics for cooking and tableware, where the element is an integral part of the microcrystalline structure of the finished ware. For many years this was the major application of petalite from Zimbabwe, and spodumene from Manitoba, Canada. These minerals constituted a large portion of the batch for these glass ceramics. Production of this kind of glass-ceramic ware has ceased, at least in North America.

Magnesia

Most MgO in glass compositions comes from dolomite or dolomitic limestone. The term “high-calcium” is sometimes applied to limestones with CaO contents of up to 56%; “dolomitic limestones” have up to 25% of the CaO replaced by MgO. In most applications the MgO serves to stabilize the glass matrix, reducing devitrification (a defect in the glass caused by crystallization of certain mineral phases) and improving mechanical and chemical durability.

Pure MgO as periclase (dead-burned magnesia) is produced from seawater or brines, either desert lake brines or deep well brines, and finds limited use in specialty glasses where the glass matrix cannot tolerate calcium. Glass ceramics, some of which are lithium-magnesium aluminosilicates, require pure grades of periclase or magnesium hydroxide. In these compositions the MgO acts as a flux and melting aid, as well as serving an essential role as an intrinsic part of the glass matrix.

Potash

Generally the term “potash” refers to various salts of potassium (Harben 2002), and specifically to the oxide K_2O . The bulk of potash consumed in specialty glasses comes in the form of potash feldspars, discussed earlier.

For glasses where potash is needed but low limits of Al_2O_3 or other alkalis preclude the use of a feldspar source, the glassmaker will resort to more expensive potassium salts such as the carbonate (K_2CO_3) or nitrate (KNO_3). Potassium carbonate is somewhat hygroscopic and can be difficult to handle and store. A hydrated form is known as “pearl ash” or glassmaker’s potash (Tooley 1984).

Potassium nitrate is generally used in CRT faceplate glass production to force the molten glass composition toward a more highly oxidized state, helping to remove any trace organics introduced with the raw materials and cullet, thus stabilizing the coloring effect of Fe_2O_3 in the glass.

Silica Sand

The specialty glass industry places special demands on the sand supplier, because in many cases the volume glass sands produced for the container industry (which consumes the bulk of glass sands) are too coarse or contain an unacceptable level of impurities.

Specialty silica sands can be specially sized—for example, 100 mesh (150 μm) for borosilicate glasses—or of greater than ordinary purity. Some of the more sophisticated glass producers

have developed proprietary theories about whether rounded sand grains or angular sand grains provide worthwhile melting benefits, and may have specification requirements relative to grain shape.

High-purity silica sands are generally considered to be those with less than 300 ppm of total impurities, while ultra-high-purity silica sands are those with less than 30 ppm total impurities.

CRT glassmakers often require 50-mesh (300 μm) sands, or even finer, to allow faster dissolution of the quartz grains, although some producers express a preference for coarser sands (35 mesh [500 μm]) to minimize the number of gas bubbles produced during the dissolution of the individual grains.

As impurities are reduced, the cost of production, recovery, and handling restrictions all increase, so ultra-high-purity grades are priced as much as US\$1/lb. The total production of such rarefied grades is relatively modest, probably not exceeding 40,000 t worldwide in 2001.

Markets for such grades of silica sand are complex, consisting of many highly fragmented and isolated individual market segments. Much ultra-high-purity silica is used to make fused quartzware. Note that fused quartz is derived from natural quartz, whereas fused silica is synthetic, being derived from chemicals such as silicon tetrachloride. About half of the quartzware is used in the semiconductor industry to manufacture crucibles for single-crystal silicon production.

Other specialty glass sectors have individual restrictions. Lead crystal makers often prefer 50-mesh (300 μm) gradings, and may have Fe_2O_3 restrictions close to the ultra-high-purity level. Large-sized art crystal pieces may require sands with Fe_2O_3 as low as 5 ppm maximum to achieve the desired clarity.

Zirconium

Zirconium is used in small amounts in a limited number of glass compositions, usually to increase the index of refraction. It also is effective in blocking x-ray transmission in CRTs and raises the viscosity and chemical durability of the glass. Zirconium is used as the refined oxide, ZrO_2 , or as the mineral zircon, $ZrSiO_4$. Zircon is one of the heavy minerals and is produced from heavy mineral sands along with the titanium minerals ilmenite, rutile, and similar dense detrital minerals (Harben 2002). Baddeleyite, a naturally occurring ZrO_2 mineral, has been produced from carbonatites by open-pit mining. It has also been reported from mineral sands.

PACKAGING AND TRANSPORTATION ISSUES

Specialty glassmakers have similar issues with packaging and transportation as do makers of other types of glass, except where limitations on contamination may demand an extra degree of cleanliness. Thus, bulk shipment of sand and feldspar, common in many glass operations, may be ruled out because shipping modes cannot be kept sufficiently free of contamination.

It is possible to achieve a surprisingly high level of cleanliness, even in bulk shipments of industrial minerals on ocean-going vessels. Bulk shipments of lithium minerals bound for specialty glass consumption have been done on bulk ocean freighters with little or no contamination, but each hold of the vessel required a special cleaning crew to remove scale and wash down the hold, followed by inspections, before the cargo could be accepted. An experienced agent of the receiving customer must do such inspections.

In a similar manner, motor trucks or railcars for bulk shipment of specialty industrial minerals may require individual cleaning and inspection by trained personnel before being certified as acceptable for use.

Many specialty glassmakers receive all their raw materials in some kind of packaging to protect them from contamination. The

most common packaging for such raw materials is the multilayer kraft paper bag with a ply of polymer film for moisture proofing. Such bags usually contain about 25.0 kg (55.1 lb) of material.

“Super sacks” of woven polymer may offer a semibulk solution to large volume materials that must be kept clean. These contain a nominal 1 ton of material, and can be handled aboard ship or on rail with relative ease. A forklift truck, for example, can lift one of the sacks for loading or unloading, or for discharge into a dump hopper.

Other containers, such as fiber drums of varying capacities, are also used where suitable, but these present some difficulty in handling. Usually a polymer film lining is included as added protection against moisture and other contaminants.

All containers of the kinds discussed here present the end user with problems of disposal, and attention must be paid to any questions of environmental or industrial hygiene hazards arising from the material contained.

CONSIDERATIONS FOR POTENTIAL SUPPLIERS

The contemporary glass industry, including specialty glass, consists of a group of producers who have survived a prolonged period of downsizing and consolidation. They are sensitive to costs, and have limited in-house resources for quality control. Industrial mineral producers wishing to become suppliers to the glass industry will be met with demands for consistency of supply, and for effective protection from upsets caused by contaminated or off-specification materials. The vendor must provide these assurances without placing undue demands on the customer's personnel.

Although the lowest possible delivered cost is a given, the glassmaker will also insist on assurances of on-time delivery of in-specification raw materials, and such assurances may be built into the purchasing agreement, with severe penalties for failure to comply.

Consequently, any industrial mineral producer seeking to gain greater penetration into the glass industry will have to be prepared to act as a provider of service rather than, or in addition to, just supplying a commodity. For example, certificates of analysis should be provided electronically to the glassmaker before the shipment arrives at the glass plant, thus avoiding any possibility of contaminating (with off-specification material) any in-specification material already in storage at the receiving plant. In fact, the vendor should reject off-specification shipments independently without waiting for the receiving plant to notice a discrepancy.

Although ISO certification alone is not proof of process control or of good quality of product, it is proof of a minimum level of record keeping, a necessary step in process control.

In many cases the specialty glassmaker will have purity or consistency requirements, or both, that are sufficiently strict to require the industrial mineral vendor to maintain an analytical laboratory capable of performing tests set forth by the glassmaker to ensure in-specification material.

A powerful marketing tool for any vendor is independent or joint research into the behavior of his industrial minerals in the glass. Forward-looking vendors should be expected to take part in glass research and raw material development, both to develop new products and to improve existing ones.

Agglomeration Processes— Pelletizing and Sintering

Joseph J. Poveromo

This chapter focuses on industrial minerals, including fluxes, used in the processes that produce iron-bearing agglomerates (pellets and sinter) for ironmaking. The predominant ironmaking process is the blast furnace, which produces liquid pig iron (hot metal) for feeding to the steelmaking vessel—an oxygen converter called the basic oxygen furnace (BOF) in North America and the L-D converter elsewhere in the world. Another important steel production process is the electric arc furnace (EAF), which relies mainly on steel scrap as a feed material. For example, in the United States, nearly 50% of the steel production is from EAF operations. Because the scrap used in EAF operations may carry As, Cu, Ni, Cr, and other deleterious contaminants, EAF operators may require additions of “clean” iron units in the form of direct reduced iron (DRI). In scrap-deficient regions, DRI may be the principal feed material. DRI is produced by the solid-state reduction of iron ore, mainly pellets, most commonly in a shaft furnace. As a prelude to the discussion of agglomerating processes, an overview of steel production and ironmaking processes is presented. All units are metric unless otherwise noted.

IRON AND STEEL PRODUCTION PROCESSES

The blast furnace continues to be the primary method of producing hot metal in large-scale steel production. Many attempts have been

made to replace it with various other process options, including direct reduction and coke-free smelting reduction. Although these new technologies are being adopted in appropriate niches, the blast furnace process has met the challenge by being amenable to continuous improvement. The current status of the competitive direct reduction processes can be summarized by noting that several (e.g., Midrex and HyL) are well established whereas others are under development but not yet fully proven. After 40 years of effort, North American (excluding Mexican) DRI production is less than 2 Mtpy whereas worldwide DRI production is about 50 Mtpy. World hot metal production, however, is more than 600 Mtpy. Thus the blast furnace process produces more than 90% of the clean (virgin) iron units. Table 1 gives world iron and steel production data from the International Iron and Steel Institute (IISI).

Growth in steel production has been dramatic in recent years, led mainly by sharp growth in China; available data indicate that world pig-iron production increased to 650.3 Mt in 2003, with the growth in China from 169 to 202 Mt being the major contributor. Steel production, based on the blast furnace process (BF/BOF), will also grow in low-cost areas such as Brazil and India, whereas regions rich in natural gas resources, such as the Middle East and Venezuela, will see growth based on the integrated DRI/EAF steel production route.

IRON-BEARING RAW MATERIALS FOR IRONMAKING

Historically, the feedstock for the world's blast furnaces was naturally occurring lump ores. The depletion of deposits of higher quality lump ores in the 1950s forced the development of low-grade ores that required fine grinding for concentration. These fine, high-grade concentrates had to be agglomerated, most commonly as sinter or pellets, ahead of the blast furnace. These agglomerates, in turn, sharply improved blast furnace performance and led to a major shift in blast furnace burdening.

Iron Ore—Sintering Ore Fines

Historically, iron ore was sourced primarily from local or regional mines. Sometimes this ore was low grade when options were limited. In the last four decades, seaborne trade of iron ore has grown dramatically, aided by the construction of large vessels and thus reduced shipping costs. Now iron ore from higher-grade ore deposits in Australia, Africa, South America, Canada, India, Sweden, and other locations can be delivered economically worldwide. The ready availability of these high-grade ores, which are ideal sinter feed, allowed steel companies to gain the advantages that uniform sinter feed can provide to the blast furnace by reducing operating costs and improving the competitive position. For most of the world, the sintering process, based on coarse high-grade ore fines, is the primary means of producing ferrous raw material feed. High-

grade ore fines are characterized by high iron content (64% to 69%), moderate levels of acidic gangue (i.e., SiO₂ and Al₂O₃ are less than 6%), low levels of key impurities (e.g., Mn, S, P, and alkalis), and trace amounts of other elements.

Iron Ore—Pelletizing

In North America, depletion of higher-grade ore reserves promoted the development of low-grade “taconite” ores, which require very fine grinding for beneficiation. These fine concentrates were not amenable to conventional sintering and led to development of the pelletizing process. The decline in hot metal production in the 1980s, along with excess modern pellet plant capacity and environmental issues, caused a reduction in sintering capacity. The subsequent development of fluxed pellets and improvement of acid pellet properties have made pellets the prime feed material in North America and parts of Europe and a valuable supplementary feed material elsewhere. Table 2 shows typical pellet chemistry.

Iron Ore—Sintering

For blast furnace operations where sinter is the principal burden material (65% to 90%), imported or local sintering ores are the prime feed material, followed by waste oxides and then fluxes. With an average iron ore SiO₂ level of 5.0%, the CaO–SiO₂ ratio is set at about 1.5 to 2.5 to ensure good sinter physical and metallurgical properties and sufficient flux to minimize or eliminate the need to charge raw flux directly to the blast furnace. The flux must contain some MgO to ensure good sinter metallurgical properties and also a certain MgO level in the blast furnace slag. The blast furnace slag MgO target varies worldwide, however, according to different strategies for slag chemistry optimization. In any event, sinter typically has the following chemistry: 55% Fe (in the form of Fe₂O₃ at 71% and FeO at 7%); 5% SiO₂; 10% CaO; 2% MgO; 1% Al₂O₃; and 4% other. This composition implies considerable (>20%) addition of raw flux, mainly in the form of limestone and dolomite, given calcination losses of about 50%.

Iron-Bearing Raw Material Usage

Sinter is the primary iron-bearing raw material worldwide. Accurate production data for sinter are not compiled, but world sinter production can be safely estimated to be well over 600 Mtpy to support pig-iron production of more than 600 Mtpy. Worldwide pellet plant capacity is about 300 Mt, but this capacity is focused in three regions: the former Soviet Union (more than 70 Mt); North America (United States, 55 Mt; Canada, 27 Mt; and Mexico, 14 Mt); and Brazil (47 Mt). Significant production also comes from Sweden (16 Mt), Iran (13 Mt), India (about 10 Mt), and Venezuela (about 10 Mt). Pelletizing capacity is growing rapidly in China (by the time of publication, this total could reach or surpass 40 Mtpy). Individual pellet plants are also operated in Chile, Peru, Netherlands, Bahrain, Japan, and Turkey. Table 3 shows long-term trends by type of iron ore.

Table 3 shows how pellet use grew dramatically at the expense of lump ore. The fine ore percentage, mainly for sinter plant use, decreased only slightly; but given the dramatic overall increase in ore production, the absolute consumption of fine ores increased sharply. Iron ore production data are now compiled for the world; total world iron ore production exceeded 1,200 Mt in 2003 (Ericsson 2004). The breakdown among ore types is not known precisely, but it is believed that the lump ore proportion is somewhat lower and pellet and fine ore proportions are somewhat higher. Sinter and fluxed pellets contribute equally well to improved blast furnace production; the choice is based on ore availability and other local economic factors. Table 4 shows iron ore consumption in 2000, by reduction process and ore type.

These data indicate that ore demand for the blast furnace route dominates the iron ore trade, but pellets dominate demand for direct reduction ore.

World Iron Ore Market

World iron ore production exceeded 1,100 Mt in 2002, with six areas (Brazil, Australia, China, the Commonwealth of Independent States [CIS], India, and United States–Canada) accounting for 86% of total output. Brazil and Australia are the largest producers, with nearly a 40% combined share; the United States and Canada together produce about 10%; China is the world's largest iron ore miner at about 230 Mt, but much of this is low-grade ore. The CIS countries of Russia and Ukraine are the third largest iron ore producer at 150 Mt. World trade in iron ore reached 500 Mt in 2002. China and Japan dominate world iron ore importing, with Asia and Europe accounting for 50% and 40% of imports, respectively.

Exports as a share of world iron ore output have been on a long-term upward trend (from 35% in 1980 to 50% in 2000), reflecting the growth and importance of ore-dependent Asia. Brazil and Australia dominate the world iron ore export market, accounting for more than 70% of seaborne exports. Other important seaborne exporters are India, South Africa, Sweden, Canada, Venezuela, and Mauritania. Russia and Ukraine export major tonnages by rail to neighboring countries.

North American Iron Ore Supply

Pellets make up 90% of North American iron ore supply, whereas sinter (10%) plays a lesser role than elsewhere in the world, largely because of environmental considerations. One pellet plant is dedicated to supplying its equity owner, Mittal Steel North America, and all the other pellet plants supply both merchant customers and equity owners (in parentheses): Minntac and Keetac (USS); Hibbing (Mittal Steel, Stelco); QCM (Dofasco); Tilden (Stelco); Empire (Ispat); and Wabush (Stelco, Dofasco). Cleveland-Cliffs dominates pellet merchant supply, selling to Algoma, Mittal Steel, WCI, Severstal NA, and other steel companies from Northshore, Hibbing, United, Empire, Tilden, and Wabush. The three Canadian producers—IOC, QCM, and Wabush—also export significant tonnage worldwide. Imports, mainly from Brazil, are less than 10% of North American supply.

AGGLOMERATION PROCESSES

Need for Agglomerates and Desired Agglomerate Quality

The blast furnace is a countercurrent gas–solid reactor in which the solid charge materials move downward while the hot reducing gases flow upward. The best possible contact between the solids and the reducing gas is obtained with a permeable burden, which permits not only a high rate of gas flow but also a uniform gas flow, with a minimum of channeling of the gas. The primary purpose of agglomeration is to improve burden permeability and gas–solid contact, and thereby reduce blast furnace coke rates and increase the rate of reduction. A secondary consideration is to reduce the amount of fine material blown out of the blast furnace into the gas recovery system.

The leading direct reduction processes such as Midrex and HyL also are shaft furnaces that rely on countercurrent gas–solid contact, so the principles of burden sizing are similar but even more important in the blast furnace, because the ferrous materials are the only solids in these furnaces.

A good agglomerate for blast furnace use should contain at least 60% iron, a minimum of undesirable constituents, a minimum of material less than 6 mm (1/4 in.) in size, and a minimum of material larger than 25 mm (1 in.). The agglomerate should be strong

enough to withstand degradation during stockpiling, handling, and transportation so as to arrive at the furnace skip containing a minimum of 85% to 95% of +6 mm (+1/4 in.) material. In addition, the agglomerate must be able to withstand the high temperature and degradation forces within the furnace without decrepitation. The agglomerate also should be able to be reduced at a satisfactorily high rate in the blast furnace. In the last several decades, different standards have developed for the two leading agglomerate forms, sinter and pellets. Table 5 is a summary of desirable sinter and pellet properties; a more comprehensive discussion is available in Kortmann, Lungen, and Ritz (1992).

Choice of Agglomerating Process

Four types of agglomerating processes have been developed: sintering, pelletizing, briquetting, and nodulizing. Sintering and pelletizing are the processes of major importance. Careful evaluation should be made of the processes, the material to be agglomerated, and the product desired before arriving at a final decision on a commercial installation. Quite often the origin of the material to be agglomerated, together with material handling and transportation considerations, will dictate which process is chosen. Fine concentrates such as those made from magnetite taconite are not easily shipped because of dusting and freezing problems, but once made into pellets, are easy to handle and transport with minimal degradation. Consequently if there is a considerable distance between the mine and the blast furnace, it is preferable to locate pellet plants near the mine site. Materials that do not have the particle-size distribution and characteristics required for pelletizing can be agglomerated by sintering. Besides natural ore fines, typical sinter feed materials include fines generated during ore transport, steelmaking slag fines, flue dust, mill scale, and concentrates that are too coarse for pelletizing. Sinter plants tend to be located near blast furnaces because sinter degrades badly during shipment and because the steelmaking facilities are the point of origin of many of the materials that can be agglomerated. For blast furnace operations relying mainly on sinter, the sinter plants are larger and fed mainly with natural ore fines. For blast furnace operations relying primarily on pellets and lump ore, the sinter plants are smaller and more reliant on in-plant recycled materials.

Energy cost and the uncertainty of fuels availability are important factors in all processes and have been the incentives to reduce fuel consumption and to use substitute fuels. Better recycling of hot gases for heat recuperation has lowered fuel costs. Additionally, converting pelletizing operations from oil and gas to coal firing has resulted in a more reliable fuel source.

The Sintering Process

Sintering has been referred to as the art of burning a fuel mixed with ore under controlled conditions. The flexibility of the process enables the converting of a variety of materials into a clinker-like aggregate that is well suited for use in the blast furnace. These include natural fine ores and ore fines from screening operations, flue dust, ore concentrates, and other iron-bearing materials of small particle size.

The continuous sintering process shown schematically in Figure 1 is carried out on a traveling grate that conveys a bed of ore fines or other finely divided iron-bearing material, mixed intimately with approximately 5% of a finely divided fuel such as coke breeze or anthracite. Near the head or feed end of the grate, gas burners ignite the bed surface and, as the mixture moves along, downdraft combustion burning the fuel pulls air down through the mixture. As the grates (or pallets) move continuously over the wind boxes toward the discharge end of the strand, the combustion

front in the bed moves progressively downward. This creates sufficient heat between 1,300°C and 1,480°C (2,370°F and 2,700°F) to sinter the fine iron-rich particles together into porous clinkers. The location along the traveling grate where the combustion front touches the bottom of the bed is called the burnthrough point. By the time the discharge end of the machine is reached, sintering will have taken place throughout the depth of the bed.

Although simple in principle, sintering plants require important design and operation criteria to attain optimum performance, and intimate mixing of the feed materials is one of the most important factors. Sintering ores, steel plant waste oxides, fluxes, and solid fuels are premixed in a bedding and blending operation in most modern sinter plants. This blended feed is supplemented by small trim amounts of flux and solid fuel. Water is then added to the total feed mixture in a mixing device such as a balling drum, or a disc or pug mill. These mixers produce small, rice-size nodules that significantly improve the permeability of the sinter bed. In many plants, burnt lime added to the feed mixture promotes granulation, especially to process ultrafine materials. Improved permeability, in turn, results in more rapid and uniform sintering. Desirable mixer retention times vary from about 1 minute for sticky hematite ores to 4 minutes for ores that are more difficult to ball.

Depending on the characteristics of the ore materials and the sintering conditions, daily average production rates of 22.4 to 42.9 t/m²/day (2.3 to 4.4 st/ft²/day) are expected, and individual daily rates in excess of 48.8 t/m²/day (5 st/ft²/day) have been achieved. The area refers to the dimensions of the grate.

Cooling the sinter below 150°C (302°F) is an important part of the operation, which allows it to be handled on conveyor belts. Sinter coolers such as the rotary type are typically used; it is best to avoid a water quench because it adversely affects sinter properties. The exhaust air from these coolers is normally too cool to permit the economical recovery of heat, although such systems have been installed in countries with high energy costs, such as in Japan.

Benefits of Fluxed Sinter to Blast Furnace Performance

Sinter is preferred to lump ore or acid pellets as blast furnace material. Improvements have been obtained (1) by incorporating the blast furnace flux into the sinter rather than charging it separately to the top of the furnace, as was formerly done; (2) by using sized sinter; and (3) by virtue of improved high-temperature properties. The available data on the use of fluxed sinter, sometimes called self-fluxing sinter, indicate that for each 100 kg (200 lb/st) of limestone per ton of hot metal removed from the blast furnace burden and charged into the sinter plant to make a fluxed sinter, approximately 10 kg (20 lb/st) of metallurgical coke per ton of hot metal are saved. The savings in coke result primarily from calcining limestone on the sintering grate rather than in the blast furnace. Limestone in the form of fluxing fines for producing sinter is made by crushing and screening methods that result in a product meeting size specifications.

Using sized sinter is desirable because it further increases iron production rates in the blast furnace. Plant tests have demonstrated significant increases in iron production rate as a result of screening out small-sized material in sinter before it is charged to the furnace.

Figure 1. Schematic flow diagram of continuous iron ore sintering process

Other tests have shown that sized sinter, which contains 85% to 90% of 25 mm \times 6 mm (1 in. \times 1/4 in.) material compared with 60% in unsized sinter, has a much higher permeability than unsized sinter and performs as well as pellets of comparable size. It also appears that crushing to -25 mm (-1 in.) at the sinter plant yields a more stable sinter because the smaller size fractions are more resistant to degradation.

In the last several decades, researchers have shown that fluxed sinter (and also fluxed pellets) has superior high-temperature properties in the blast furnace compared to lump ore and acid pellets. These improvements include higher softening and melting temperatures and higher levels of reducibility.

The above description of sintering is only an introduction to the topic. Earlier references (before 1980) are useful for North American and former Eastern Bloc sinter plant operations, most of which were built in the 1950s and 1960s. Some more recent references describe advances in sintering relevant to large, modern sinter plant operations, which are predominant in Europe and the Asia-Pacific area.

It has been demonstrated in North America and in the Scandinavian countries that blast furnace performances with fluxed, sized sinter also can be achieved with pellets that are properly sized and fluxed with either limestone/dolomite mixtures or olivine.

Pelletizing—General Considerations

Pelletizing differs from sintering in that a green unbaked pellet or ball is formed and then hardened by heating. Experimental work on the concentration and agglomeration of low-grade iron ores, started many years ago by E.W. Davis and his associates at the University of Minnesota, showed that it was possible to ball or pelletize fine magnetite concentrate in a balling drum, and that if the balls were fired at sufficiently high temperature (usually below the point of

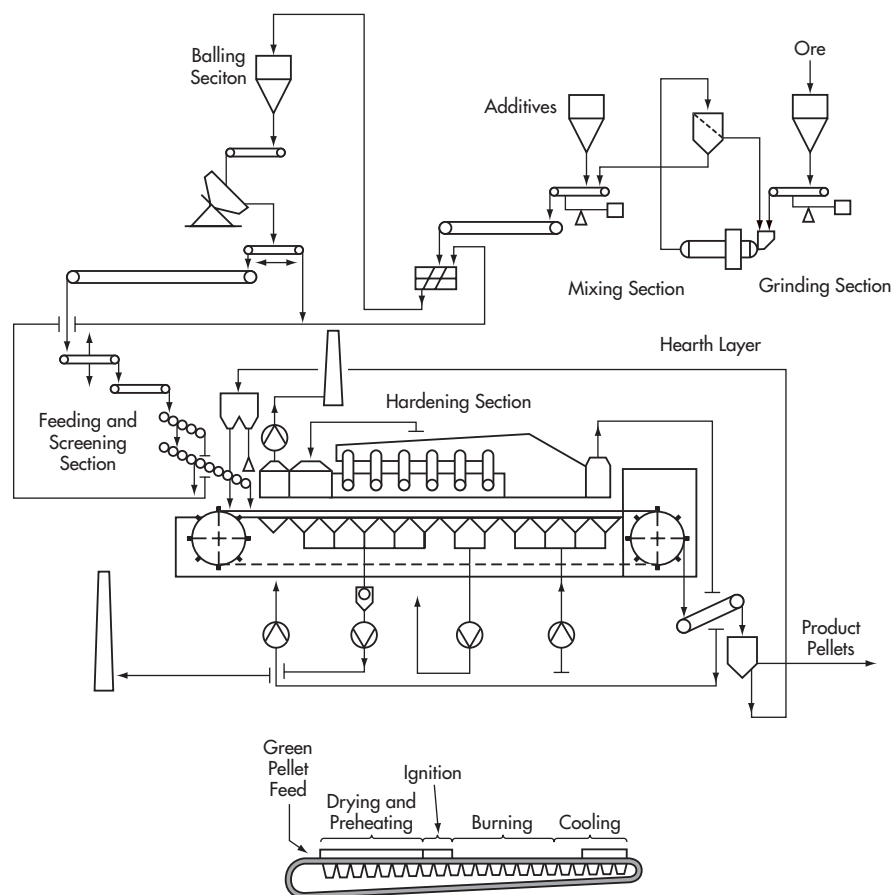

incipient fusion), a hard, indurated pellet could be made that was well adapted for use in the blast furnace. Consequently, despite the unquestioned benefits of sinter on blast furnace performance, intense interest in the pelletizing process had developed because of the outstanding performance achieved by steel producers in extended operations with pellets as the principal iron-bearing material in the blast furnace burden. In North America this interest was promoted further because of the absence of coarse sintering ores coupled with the opportunity to effectively use abundant reserves of low-grade taconite ore.

In general, the pelletizing process is desirable for agglomeration of finely divided concentrates because they are normally of a size that can be formed into a green ball with little difficulty. Concentrates and high-grade ores not suitable for pelletizing are in some cases ground to the required size when pellets are desired as the final product.

Pelletizing Feed Preparation

The balling drum and the disc pelletizer are the most widely used devices for forming green balls. Compared with the balling drum, the disc has the advantages of lighter weight and greater possibility for adjustment. Its inherent design averages out the effect of instantaneous fluctuations in the feed, whereas the drum cannot. Also, the classifying action of the disc promotes discharge of balls of more uniform size. The capacity of the discs is low, however, and discs generally require closer control than drums. Best control of ball size is achieved when the balling device is in closed circuit with a screen to remove and recycle the undersize material.

Binders such as bentonite clay or hydrated lime are generally used to raise the wet strength of green balls to more acceptable levels for handling. Bentonite consumption at 6.3 to 10 kg/t of feed is a significant cost element and adds to the silica content of

Source: Reprinted with permission from *The Making, Shaping, and Treating of Steel*, 11th edition. Edited by D.H. Wakelin. Chapter 8, Iron Ores, written by J.J. Poveromo. Copyright 1999, by the Association for Iron & Steel Technology.

Figure 2. Schematic diagram of the traveling grate system for iron ore pelletizing

the final product. Considerable effort has been directed at reducing bentonite usage and developing cheaper substitutes. The ballability and strength of green balls are influenced by the additives and the moisture content and particle-size distribution of the concentrates. Optimum moisture content for good balling is usually in the 9% to 12% range. It appears that balling characteristics are relatively independent of the chemical composition of a concentrate but strongly affected by its physical properties. For example, specular hematite is more difficult to ball than are magnetite concentrates because of the plate-like structure of the former. In any case, satisfactory pellet formation usually is achieved by regrinding to about 80% to 90% of $-43\ \mu\text{m}$ (-325 mesh). Normally any material considered for pelletizing should contain at least 70% of $-43\ \mu\text{m}$ (-325 mesh) and have a specific surface area (Blaine) $>1,200\ \text{cm}^2/\text{g}$ for proper balling characteristics.

Both the drop and compressive strengths of green pellets are important, but compression strength is most important because dried pellets are not required to withstand much handling. The strength of fired pellets is important in minimizing degradation during handling and shipping, and in the blast furnace. Strong bonding in pellets is believed to be caused by grain growth from the accompanying oxidation of magnetite to hematite or recrystallization of hematite. Although slag bonding may promote more rapid strengthening at slightly lower firing temperatures, pellet strength is normally decreased, especially its resistance to thermal shock. Fired pellet

strength is determined most commonly by compression and tumble tests. Compressive strengths of individual pellets depend on the mineralogical composition and physical properties of the concentrate, the additives used, the balling method, pellet size, firing technique, and temperature. The compressive strengths of commercially acceptable pellets are usually between 200 kg and 350 kg for pellets between $-13\ \text{mm}$ and $+9\ \text{mm}$. In the tumbler test, 11.4 kg (25 lb) of $+6\ \text{mm}$ pellets are tumbled at 25 rpm for 8 minutes in a drum tumbler (ISO 3271: 1995) and then screened. A satisfactory commercial pellet should contain no more than about 5% of $-0.6\ \text{mm}$ (-28 mesh) fines, and 94% or more of $+6\ \text{mm}$ size, after tumbler testing. A minimum of broken pellet fines between 6 mm and 0.6 mm is also desirable. Other important properties of fired pellets for blast furnace feed are reducibility, porosity, and bulk density.

Pellet Plant Flowsheet

The flowsheet of a pelletizing process is similar in many respects to the sintering process, particularly in the materials handling area. Usually the associated mining, concentrating, and grinding installations are operated as a feed preparation section of the pellet plant. The three most important pelletizing systems are the traveling grate (Figure 2), the grate-kiln (Figure 3), and the shaft furnace. Figure 2 shows the overall layout of the pellet plant for the traveling grate system; it would be the same for the other indurating systems. Each system has been used commercially to make quality pellets, and so

capital and operating costs are usually the deciding factors involved in choosing one or the other. Fuel requirements for these pelletizing systems vary from about 500,000 to 1 MkJ/t of pellets, depending on the feed material. Oxidizing magnetite to hematite during pelletizing will produce a significant proportion (about 400,000 kJ/t) of the heat requirement in all of the systems. For pelletizing hematites, using coke breeze (or some carbon source) in the pellet feed mixture has become a common practice, producing the additional endothermic energy normally produced by magnetite oxidation. Pelletizing processes are being improved constantly, and sources in the bibliography give further details on their technology and development. Self-fluxing pellets is an example of an innovation that has been accepted on a commercial scale and has led to major advances in blast furnace performance.

Traveling Grate

The traveling grate system for producing pellets, illustrated in Figure 2, is essentially a modification of the sintering process. The green balls are fed onto the grate continuously to give a bed depth of about 300 to 400 mm (12 to 16 in.) and are dried in the first few wind boxes by updraft air recovered from the firing zone; this is followed by downdraft drying using recovered air from the cooler. This arrangement of hot air flow limits pellet damage from condensation of moisture in the bed. Following drying, downdraft air from the cooling zone preheats the pellets. Firing is done downdraft in the combustion zone by burning fuel oil or natural gas with hot air from the cooling zone. The cooling zone follows the combustion zone and uses updraft fresh air.

Fuel consumption in the traveling grate system is about 350,000 to 600,000 kJ/t of pellets produced from magnetite and up to 1 MkJ/t from pelletizing hematite. The system offers good temperature control in the firing zone. Pellet consistency throughout the bed is achieved by recirculating some fired pellets to form hearth and side layers on the grate. The largest grate machines are 4 m (13 ft) wide and can produce more than 3 Mt of pellets per year. Circular grate machines also have been designed, and one such machine is in operation.

Grate-Kiln System

The grate-kiln system, depicted in Figure 3, consists of a traveling grate for drying and preheating the pellets to about 1,040°C (1,902°F), a rotary kiln for uniformly heating the throughput to the final induration temperature of 1,315°C (2,400°F), and an annular cooler for cooling the product and recuperating heat. A central oil, gas, coal, or waste wood burner at the discharge end of the kiln supplies heat for firing. Hot gases produced in the kiln are used for downdraft preheating of the pellets. Hot air from the cooler supports combustion in the kiln; it also is recovered to the traveling grate for drying and tempering preheat.

The grate-kiln system offers excellent temperature control in all stages of the process and produces a consistently uniform product. Fuel consumption is 300,000 to 400,000 kJ/t of standard pellets produced when using magnetite ore and up to 700,000 kJ/t of standard pellets produced when the feed is hematite. Fuel consumption increases by 250,000 kJ/t when producing fluxed pellets. Power consumption, from balling to pellet loadout, is 23 kW-hr/t. Grate-kiln systems can be designed for production tonnages up to 6 Mtpy per line.

Briquetting

Briquetting is an old art of agglomerating or forming small or large lumps of regular shape from a wide variety of materials, including wood, coal, lignite, chars, cokes, ores, and flue dust. Various designs

Source: Reprinted with permission from *The Making, Shaping, and Treating of Steel*, 11th edition. Edited by D.H. Wakelin. Chapter 8, Iron Ores, written by J.J. Poveromo. Copyright 1999, by the Association for Iron & Steel Technology.

Figure 3. Schematic diagram of the grate-kiln system for iron ore pelletizing

of punch and roll presses are or have been used. Briquetting of cold or unheated material had not been successful for producing satisfactory agglomerates for the blast furnace until recently. Briquettes usually are formed using a binder and do not possess the strength that high-temperature heating gives pellets and sinter. The shutdown of sinter plants in North America and Scandinavia has led to improvements in briquetting technology by recycling waste oxides. Such briquettes can be used at 3% to 10% of the furnace burden without difficulty; the poor high-temperature properties preclude higher consumption levels.

Consumption of Fluxes in Sintering

The level of flux consumption in sintering can be estimated from data from sinter plant operations in Asia, Europe, and North America. The fluxes used are limestone, dolomite, olivine, serpentine, and burnt lime.

Limestone

Limestone is composed primarily of the mineral calcite (CaCO_3) and is the most widely used flux. Its calcium combines with iron to form calcium ferrites that bond sinter particles together and give the sinter the physical strength and high-temperature properties that are desirable in blast furnace raw material. Limestone consumption rates average between 100 and 125 kg/t of sinter. With sinter production exceeding 600 Mtpy, limestone consumption would exceed 60 Mtpy accordingly and could approach 90 Mtpy worldwide. Limestone deposits are common, so for any given operation it is sourced locally or regionally. The chemical and physical specifications for limestone (and dolomite) are listed in the chapter on metallurgical fluxes in this volume. For limestone, the key physical attribute in sintering is a size range of 1 to 3 mm. Particles that are too coarse will not melt and be assimilated properly into the sintered matrix, whereas ultrafine particles may be carried through to the sinter waste gas system.

Olivine (Serpentine, Dunite)

Olivine (solid solution series composition: Mg_2SiO_4 and Fe_2SiO_4) fluxes are used selectively worldwide. The objective is to achieve the desired MgO level in blast furnace slag, and the SiO_2 helps increase the final sinter SiO_2 target level to about 5% or higher. The

sinter SiO_2 by itself is helpful only to the extent that it allows an increase in total CaO input at a given target CaO/ SiO_2 level. The CaO helps to “hold the sinter together,” and the CaO/ SiO_2 ratio must be high enough to flux the iron ore gangue and coke ash compounds in the blast furnace raw materials. The upper limit of the CaO/ SiO_2 ratio in sinter (and therefore blast furnace slag) is limited by slag viscosity and slag alkali removal considerations. Typical sinter CaO/ SiO_2 levels are between 1.5 and 2.2 depending on the overall sinter percentage. The SiO_2 input is required for European and Asian sinter plants that use large amounts of iron ore from Brazil and Sweden, which have low SiO_2 levels. The prime Australian ores also have SiO_2 levels well below 5%.

Olivine and serpentine are more desirable sources of MgO than dolomite because olivine does not require calcination; serpentine, however, does require the removal of water. These materials are viewed as enhancements to the sintering process, whereas dolomite is regarded as detrimental and necessary only to meet blast furnace slag chemistry requirements. Both MgO sources improve the high-temperature properties of sinter.

Olivine is a magnesium-iron silicate with an average composition of 93% forsterite (Mg_2SiO_4) and 7% fayalite (Fe_2SiO_4). A typical chemical composition follows:

Oxide	%	Oxide	%
MgO	49.0	Al_2O_3	0.5
SiO_2	41.0	NiO	0.3
FeO	7.0	MnO	0.1
Cr_2O_3	0.3	CaO	0.05

Olivine composition can range from 100% Mg_2SiO_4 to 100% Fe_2SiO_4 because it is a solid solution series. The melting temperature of fayalite is low, so the Mg:Fe ratio in olivine is one of the critical specifications in assessing the suitability of different olivine compositions for use as fluxing agents. Additional details are given in the chapter on olivine in this volume.

Typical addition rates for olivine are 25 to 40 kg/t in European sinter mixes. Use of olivine to replace dolomite began in 1975 in Europe and is now universally accepted. European consumption is estimated at 3 Mtpy and is sourced mainly from Norway.

Dunite is a rock composed primarily of olivine, whereas serpentine is a hydrated magnesium-iron silicate. The Fe:Mg ratio varies from one deposit to the next. Generally, the chemical specifications apply as they do for olivine.

The choice of olivine, dunite, or serpentine depends on availability and logistics. Olivine is readily available in the Atlantic basin, mainly from Norway; dunite and serpentine are more readily available in the Asia-Pacific regions.

Dolomite

Dolomite is used mainly in North American sinter mixes to achieve the desired MgO level in the blast furnace slag. Worldwide, some dolomite is used in Asia and Europe. In North America, only one sinter plant operation, which uses significant amounts of low-silica Brazilian ore (Operation A in Table 6), uses olivine. The remaining operations achieve adequate SiO_2 levels from recycled materials such as steelmaking slag, so any additional SiO_2 from olivine would be detrimental. Therefore dolomite is the convenient choice for addition of MgO as well as for CaO. The chemical and physical specifications for dolomite are given in the chapter on metallurgical fluxes in this volume.

Burnt Lime

Burnt lime is introduced as a binder in the sinter plant mixing drum to promote the agglomeration of ultrafine particles (0.1–1.0 mm).

The objective of using the mixing drum is to add the proper amount of water and binder (burnt lime) to promote agglomeration so that the particles will exceed 1 mm in diameter when they exit the mixing drum. Such particles enhance the permeability of the mix, increasing gas flow and thus accelerating sintering. Using burnt lime is particularly effective when the sinter mix contains significant levels of finer sized iron ore concentrates and other fine ores. Burnt lime is used extensively in European sinter plants and to a lesser extent in Asian sinter plants, where the predominant feed materials are coarser Australian iron ores. Burnt lime is used in only one plant in the United States, which is shown as Operation A in Table 6.

Typical consumption rates for burnt lime are 5 to 15 kg/t of sinter. A rule of thumb is that a 1% addition (10 to 15 kg/t) increases sinter production by as much as 10%; the incremental benefit at higher addition rates, however, is much lower. Because burnt lime is more costly than other flux materials, most sinter plant operators target burnt lime addition rates at about the 1% level.

Burnt lime is identical to the high-calcium lime used in steel-making in the BOF, as described in the chapters on fluxes in this volume; the chapter on lime gives additional information.

Other Industrial Mineral Applications in Sintering

The only other known application of industrial minerals in sintering is spraying a solution of CaCl_2 onto the hot sinter as it exits the sinter strand. The objective is to increase the reduction-degradation index (RDI) of the sinter. This metallurgical property of sinter is important in avoiding excessive generation of fines in the upper stack of the blast furnace during the initial reduction of hematite to magnetite. Only a few sinter operations worldwide use this technique.

Consumption of Binders, Fluxes, and Coatings in Pelletizing

Additives to the iron ore mixture in pelletizing include binders and fluxes. The fluxes mainly modify the chemical composition of the slag-forming constituents of pellets; some of these additives such as lime and magnesium lime compounds, and siliceous compounds such as quartz and olivine, also may have binding properties. Some recycled materials called “reverts” also may have binding properties, but the use of such steel plant oxides is limited.

Binders

Binders help form pellets and maintain their strength before and after firing. The type of binder used depends on the type of ore to be pelletized. Finely ground natural ores with clay-like textures are readily agglomerated and require little or no binder addition. Such ores typically have significant Al_2O_3 levels that provide this clay-like behavior; these ores are found in Venezuela, Australia, India, and, to a lesser extent, Brazil. Iron ore concentrates produced from the beneficiation of taconite ores in the United States and specular hematite ores in Canada are not readily self-agglomerating and so require binders. The binders aid agglomeration and impart sufficient strength to unfired green pellets.

Table 7 lists binder use for selected pellet plants in North America and in world plants, i.e., those in South America, Europe, and the Asia-Pacific regions. Bentonite use is predominant in North American plants, but its use is also significant in some pellet plants overseas. One North American plant has been able to replace bentonite with an organic binder. Other materials used as binders are hydrated lime and caustic soda. Many other materials such as peat moss, starch, bitumen, and others have been proposed as binders, but only three have found widespread use: bentonite, hydrated lime, and organic binders.

Bentonite

Bentonite is the binder of choice in North America and is extensively used worldwide as well. Consumption rates fall in a narrow band of 8 to 10 kg/t, except where other binders supplement bentonite. The total consumption in North America would be just above 500,000 t, with the U.S. pellet producers supplied mainly from Wyoming and the Canadian pellet producers supplied mainly from the Greek island of Milos and also from India. Bentonite is described in more detail in the chapter on bentonite clays: in this volume. Bentonites used in pelletizing are the active sodium type from Wyoming and the sodium exchanged calcium type from Greece. The latter type is prepared by ion exchange of Ca⁺⁺ for Na⁺ by simply mixing it with soda ash. With both types, the bentonite expands with addition of water and promotes migration of water into iron ore particles; this in turn promotes agglomeration during the balling step. As the green balls are being indurated, bentonite promotes the formation of a slag bonding phase; this ultimately is responsible for the high strength of the fired pellet.

Bentonite is a rock composed primarily of clay minerals of the smectite group (including montmorillonite), which has the capacity to adsorb large volumes of water and expand to several times its original volume. This swelling property and the high thixotropic behavior are the most important characteristics for the bonding capacity of bentonite. The swelling capacity is defined by the Enslin value:

$$E_w = (V \times 100)/P$$

where

E_w = Enslin value, in %

V = absorbed water quantity, in cm³

P = bentonite quantity, in g

The chemical composition of various bentonites includes the following ranges of major components: SiO₂ (43.0% to 72.0%); Al₂O₃ (3.0% to 20.0%); Fe (0.67% to 14.0%); CaO (1.0% to 1.8%); MgO (2.0% to 3.5%); Na₂O (0.04% to 3.0%); K₂O (0.1% to 1.7%); and loss on ignition (LOI; 5.0% to 11.0%). The specific surface

§ Direct reduction.

area ranges from 3,000 to 8,000 cm²/g, whereas Enslin values range from 200% to 900%.

Bentonite contains alkalis such as Na₂O and K₂O, which are undesirable in the blast furnace, and SiO₂ and Al₂O₃, which are expensive to remove in the electric furnace (for direct reduction [DR]-grade pellets). Accordingly, some of the efforts to reduce bentonite consumption or to find substitutes for bentonite are driven by the desire to reduce the input of these undesirable elements into ironmaking and steelmaking furnaces.

Hydrated Lime

Hydrated lime (Ca(OH)₂) can be used with ores that already have some propensity for self-agglomeration. It is produced from limestone and is usually sourced locally; it is also less expensive than bentonite. Hydrated lime is discussed in the chapter on lime in this volume. Briefly, CaO is obtained by calcining limestone at temperatures >900°C (1,652°F). Calcium hydrate is produced from CaO by slaking with water. The oxide is converted to hydroxide in quenching units, and is then pulverized. Hydrated lime is transported in closed containers.

Hydrated lime acts as both a binder and a basic additive. During pellet induration, the basic additives react first with the “acid” gangue constituents to form a neutral or basic matrix between the iron oxide grains. Accordingly, hydrated lime has some advantage over bentonite, which adds acidic gangue to the pellet mix.

During the mixing process, hydrated lime greatly increases the specific surface area of the iron ore mixture. This in turn contributes to increased wet green ball and dried fired-pellet strength, even with more coarsely ground ores.

This substance, however, is less capable than bentonite of controlling water during pelletization and does not contribute to the cohesive/adhesive forces required to form and maintain green pellet integrity.

Organic Binders

Organic binders have been under development for some time and continue to be investigated. They are used both as the sole binder additive and in conjunction with others. These binders immobilize large amounts of water during the pelletization process and then release this water gradually during the drying process. They offer some key advantages relative to bentonite such as reduction of acidic gangue input and increased porosity, which can contribute to increased pellet reducibility and improvements in other metallurgical properties. The increased porosity results from burning off the organic binder during the indurating process.

The increase in porosity also poses challenges in maintaining fired-pellet strength; this has been one of the major roadblocks to more widespread use of organic binders. Fired pellet strength can be maintained with skillful modification of green-balling and indurating conditions, and also by using other additives such as limestone.

The two principal types of organic binders are one based on cellulose and the other based on a polymer. Both are noncontaminating to the iron ore pellets and contain no elements (such as sulfur, phosphorus, and alkalis) that are harmful in ironmaking and steelmaking. These binders produce carbon dioxide and water vapor when burned.

Organic binders are shipped as fine powders of <200 mesh. They are added directly in front of the balling step. Typical addition rates are 0.3 to 0.6 kg/t (0.03% to 0.06%). Such rates are about 10% of a typical bentonite rate, but the costs of these manufactured specialty chemicals are usually 10 times greater than bentonite.

Accordingly, the major incentives for using organic binders are focused on their benefits in ironmaking and steelmaking. In direct reduction ironmaking, the advantages are mainly realized in the subsequent electric furnace steelmaking step, where every 1.0% reduction in pellet SiO₂ content can reduce liquid steel costs from \$3.00 to \$5.00 per ton of DR pellet. In the blast furnace, an increase in pellet reducibility of 0.1% in the ISO R40 test (range of reducibility: 0.5 to 1.3) can decrease the coke rate by 5 kg/t and therefore reduce hot metal cost by \$0.50/t of hot metal or nearly \$0.75/t of pellets for an all-pellet burden.

Fluxes: Flux Additions to Blast Furnace Grade Pellets

The principal fluxes used in pelletizing are limestone, dolomite, and olivine. The other major additive used in pelletizing is coal, particularly for hematite pellets. Table 8 gives typical consumption levels. Fluxes can be broadly divided into three major categories: dolomitic-limestone, limestone, and olivine.

Dolomitic-Limestone Fluxed Pellets

Dolomitic-limestone fluxed pellets predominate in North America. Commercial pellet production began in North America in the 1950s with production of acid pellets (SiO₂ = 5% to 6%) with the sum of CaO and MgO <1.0%. Such pellets provided blast furnace performance that was superior to the use of lump ore but inferior compared to high-quality fluxed sinters. Research studies showed that pellet metallurgical properties such as reducibility, high-temperature softening, and melting temperatures could be increased with basic additives. Indeed, overseas pellet producers (e.g., in Japan) successfully demonstrated production and use of dolomitic fluxed pellets; in

§ Acid.

North America, however, it was not until the mid-1980s that researchers identified the right combinations of limestone and dolomite to improve metallurgical properties while maintaining satisfactory physical properties. By the early 1990s, most North American pellet plants were modified to produce fluxed pellets. The CaO–SiO₂ ratio is typically 0.9 to 1.0 but can be increased to 1.3, whereas MgO levels range from 0.6% to 1.8%. The MgO target specification determines the ratio of dolomite to limestone in the flux mixture. On a worldwide basis, dolomitic fluxed pellets are gaining popularity at the expense of limestone fluxed pellets.

Limestone Fluxed Pellets

Limestone fluxed pellets are still produced in some parts of the world, including Brazil. In some cases, adding limestone was an extension of using calcium hydrate as a binder. Depending on the ore type, limestone also may improve the physical and metallurgical properties of the pellets.

Olivine Fluxed Pellets

Olivine fluxed pellets play a key role in areas such as Sweden and the Netherlands where some Swedish ores are pelletized. In these areas, the ores being pelletized are very low in SiO₂. Producing an acid pellet from such ores could result in very high swelling values. Olivine is a convenient mineral that contributes both SiO₂ and MgO; the MgO improves the metallurgical properties of these pellets and the overall silicate structure gives them high physical strength. In the Asia-Pacific area, other types of magnesium-silicates such as serpentine (see Table 8) play the same role as olivine.

Flux additives also are playing an increasing role in improving the properties of acid pellets. Adding 1% to 2% of either limestone or dolomite can improve key physical and metallurgical properties such as tumbler and compression strength and resistance to swelling and low-temperature breakdown. Table 8 gives typical addition rates for blast furnace fluxed and acid pellets.

The data in Table 8 suggest total flux addition rates of about 100 kg/t, or 1.0%, for dolomitic fluxed pellets and <50 kg/t for limestone fluxed and olivine fluxed pellets. The lower addition rates for the latter are related to the lower SiO₂ levels of the ores being pelletized; this in turn requires less flux addition to achieve a given basicity target.

These flux additions do not dramatically affect green-ball formation but do play an important role during induration. The fluxes are ground to the same level of fineness as the ores being pelletized, preferably with separate grinding facilities. During induration the limestone reacts with the acidic gangue to produce a slag bonding phase and the dolomite reacts with the ore to produce a magnesian-wustite bonding phase. The resultant increase in porosity contributes to increased reducibility and the combination of slag bonding and oxide bonding contributes to the increase in softening and melting temperatures. In acid pellet production at elevated temperatures, wustite (FeO) combines with siliceous gangue to form low-melting temperature fayalite. This in turn increases contraction and extends the softening–melting temperature range.

For blast furnace acid pellet production, the primary additive is limestone, about 1% to 2% (10 to 20 kg/t). This increases pellet strength by creating a stronger slag bonding phase in the pellet. Some pellet producers also add up to 1% (10 kg/t) dolomite, which contributes mainly by its resistance to swelling.

Flux Consumption in Blast Furnace Pellet Production

North American fluxed pellet consumption is about 45 Mtpy. With flux consumption levels at about 10%, this implies consumption of limestone and dolomite together is > 4 Mtpy. The lesser use of fluxes in acid pellet production could bring this total to some what <5 Mtpy. Such fluxes are usually obtained from local or regional sources. The specifications for limestone and dolomite are in the chapters on metallurgical fluxes in this volume.

Benefits of Fluxed Pellets to Blast Furnace Performance

The effect in the blast furnace of improved metallurgical properties of fluxed sinter or fluxed pellets (as compared to acid sinter, acid pellets, or lump ore) is a lower coke rate because of the combined benefits of improved reducibility and improved high-temperature properties. The latter manifest themselves in the shift of the blast furnace “cohesive” zone (where the iron-bearing raw materials initially soften and then melt off as liquid hot metal and slag). This shift of the cohesive zone lower in the furnace and closer to the furnace center increases the volume of the zone where gaseous reduction of iron oxides occurs. It is not possible to allocate the coke rate savings between the reducibility and cohesive zone shift phenomena. The shift in the cohesive zone also provides other process economic benefits, specifically extension of furnace campaign life as a reduced volume of hot gases strike the furnace wall, and reduction in hot metal silicon content (with attendant downstream benefits in the steelmaking BOF) as the volume for Si transfer in the furnace is reduced.

In blast furnace practice, the benefits of fluxed pellets relative to acid pellets include both reduced raw flux calcination and improved metallurgical properties. For converting a burden of 100% acid to a burden comprising at least 65% fluxed pellets, the process benefits could be quantified as follows.

- Coke rate savings of 25 to 30 kg/t hot metal owing to a combination of technical reasons: reduction of raw flux calcinations, improved pellet reducibility, cohesive zone shift, and ability to operate at higher flame temperatures. This is about twice the savings calculated for an acid pellet burden solely because of raw flux calcinations.
- Extension of campaign life through reduced lining wear as a result of reduced gas flow and thermal load at the furnace walls.
- Reduction in hot metal Si content caused by cohesive zone shift with attendant benefits in BOF operations.

The statement that the process benefits are realized with at least “65% fluxed pellets” is based on the observation that once the burden composition exceeds 65% of a dry iron-bearing material, the furnace behaves as if the entire iron-bearing component was that one material. Accordingly, most ironmakers operating with all-pellet burdens use about 65% to 80% fluxed pellets, with the balance mainly acid pellets. This practice also maximizes the consumption of other basic materials such as waste oxides like steelmaking (BOF) slag.

Although flux pellets account for about two thirds of North American pellet production, acid pellets still play a key role as a supplement to predominantly fluxed pellet or fluxed sinter burden or even in all-pellet operations where the plant hot metal requirement can be met by an all-acid-pellet burden.

Flux Additions to DR-Grade Pellets

Flux additions to DR-grade pellets are also significant, although less so in recent years. Table 9 lists some flux addition rates for DR-grade pellets. At one time, a number of DR-grade pellet producers, mainly in Brazil and Sweden, added about 5% of flux to reduce the “sticking” or “clustering” tendency of pellets during reduction in Midrex or HyL shaft reduction furnaces. As DR-grade pellets underwent reduction, metallic whiskers formed and attached or stuck to whiskers from adjacent pellets, forming clusters that could impede the downward flow of reduced pellets. The flux additions coated the metallic whiskers, thus minimizing cluster formation.

The development of pellet coating techniques provided a more cost-effective means of eliminating pellet clustering in DR shaft furnaces. Although additives such as CaO and MgO provided fluxes that would be used later in EAF steelmaking furnaces, adding higher levels of fluxes also reduced the Fe content and increased pellet costs. At present most DR pellet producers add 1% to 2% (10 to 20 kg/t) fluxes, mainly dolomite, to enhance pellet physical and metallurgical properties. Coal addition rates of 10 to 20 kg/t help meet indurating energy requirements for these predominantly hematite ores.

Coatings for DR-Grade Pellets

In the mid-1990s, pellet producers and shaft furnace operators worked together to develop and implement the concept of “coating” pellets. Pellet coating mixtures, mainly aqueous, of various finely ground oxides would be sprayed onto pellets as they exited the indurating furnaces. Such coatings are limestone, dolomite, bauxite, cement, and other substances. These coatings also can be applied just before pellets enter the Midrex or HyL shaft furnaces. In some practices, the pellets are coated twice, once at the pellet plant and then again just before the reduction furnace. By coating the surface of the pellet, metallic whiskers are encapsulated by the oxide coating.

Because of coatings technology, shaft furnaces are able to operate at higher temperatures (760°C [1,400°F] to as much as 1,000°C [1,832°F]) to increase both metallization and productivity. Furthermore, this ability to operate at higher shaft temperatures has encouraged the use of techniques such as oxygen enrichment that raise the bustle (inlet) temperature to these furnaces; this in turn increases the shaft temperature. Increases in productivity of 10% to 15% can be achieved and increases in metallization from 92% to 95% have also been realized. The EAF steelmaking furnace benefit of increased metallization is about \$0.70/t of DR pellet per 1% increase in metallization.

Table 10 gives some current coating practices.

Although coatings have been applied mainly to DR-grade pellets, one pellet producer has been exploring coatings for blast furnace pellets. The incentive is to minimize dust generation in the blast furnace shaft, improve furnace permeability, and increase pellet yield as flue dust generation is decreased.

Other Pelletizing and Briquetting Applications: DR and Alternative Ironmaking

Nearly all sintering and pelletizing applications in iron and steel production involve preparing iron-bearing raw materials for the major established reduction processes: the blast furnace and the

gas-based DR processes, Midrex and HyL. The latter account for more than 90% of the DRI production worldwide; some agglomeration applications, however, relate to other ironmaking processes to produce either liquid hot metal or DRI.

Corex Process

The same pellets used for the DR processes are also used in the Corex ironmaking process. Corex is a two-step process in which the prereduction step is a shaft furnace fed with pellets and lump ore on top and with a reducing gas on the bottom. This reducing gas is the off-gas (top-gas) from the smelting reduction vessel, which is fed with coal and oxygen. Commercial Corex hot metal plants are in operation in South Africa, India, and Korea; the total tonnage is <5 Mtpy. High capital costs are a barrier to widespread adoption, but additional Corex plants are expected to be built in regions where power generation from excess off-gas from this process may be as valuable as the hot metal produced.

Rotary Hearth Furnace Processes

Another class of processes to use fine iron ores is the rotary hearth furnace (RHF) DR processes. These processes require either a briquetting or a pelletizing step to prepare self-reducing agglomerates of iron ore fines, coal fines, waste oxides, binders, and fluxes for the RHF. These agglomerates are heated and reduced in one circumferential trip around the rotary hearth. The DRI produced can then be melted in a subsequent EAF or BOF steelmaking process or even in a blast furnace. In some process variants such as the Iron Dynamics, Inc. (IDI) process, the RHF is coupled to a submerged arc furnace (SAF). The hot DRI produced in the RHF is charged directly into the SAF to produce liquid hot metal for subsequent charging into an EAF. Another variant is the ITmk3 process in which the RHF is heated to a sufficiently high temperature to separate the reduced agglomerate into molten pig iron and slag while still on the RHF. The resultant pig-iron nugget can then be charged to an EAF. Both the IDI and ITmk3 processes are headed toward commercial development in the United States. The overall effect on flux consumption may not be significant, however, because the SAF and EAF process steps will still require fluxes for proper slag chemistry. Binders continue to be used to produce satisfactory self-reducing agglomerates. Other RHF processes use steel plant waste oxides along with some coal to produce a lower grade solid DRI product for subsequent use in an EAF, BOF, or blast furnace. Smaller scale (<300,000 tpy) RHF plants using various technologies (e.g., Fastmet, DryIron, Inmetco) are in commercial operation in the United States, Japan, and elsewhere.

Cold Bonding Processes

In some commercialized cold bonding processes, steel plant waste oxides, ore fines, coal/coke fines, etc., are agglomerated to produce a material suitable for charging into a blast furnace or cupola. The agglomeration process is usually a briquetting process, although pelletizing and brick-forming processes also have been developed. The produced agglomerate lacks the high-temperature strength of fired agglomerates such as sinter or pellets. Accordingly, such cold-bonded agglomerates can be used only as <5% of the iron-bearing charge to a blast furnace; otherwise blast furnace permeability and overall performance will be adversely affected. Therefore the scale (usually <100,000 tpy) of such plants is limited by both the consumption ability of the blast furnace and the availability of waste oxides in a given steel plant. The use, if any, of industrial minerals in these processes is usually for binders, with materials such as cement, molasses, and various proprietary mixtures commonly employed.

† Blank cells indicate a value of zero.

Examples of such cold-bonded processes include several steel plants in North America without sinter plants that are using briquetting processes operated by outside companies to produce waste oxide briquettes composed of mill scale, ore fines, dusts, sludges, coke breeze, etc. In Sweden, a brick-forming processor consumes similar materials. In Japan, all steel companies have sinter plants, but cold-bonded pellets are made up of waste oxides not suitable for the sintering process.

All of the above produce agglomerates for blast furnace consumption. In Germany, a commercial plant (OxiCup Process) is being built to process “self-reducing” bricks (composed of waste oxides, coke breeze, etc.) in a cupola to produce liquid hot metal.

Alternative processes have a key objective of using iron ore fines (as well as waste oxide and coal fines in some cases) without relying on any prereduction process.

Hismelt, Smelting-Reduction Processes

Long-standing efforts to replace the blast furnace process are aimed mainly at replacing coke ovens and sinter plants and other processes that prepare raw materials for the blast furnace. The blast furnace itself is a highly efficient, environmentally compliant process. Alternative processes to the blast furnace involve smelting-reduction processes fed with iron ore fines, flux, and coal fines. The leading candidate is the Hismelt process, with commercial plants capable of producing 0.5 Mtpy of pig iron or hot metal starting up in Australia and China. Such plants would feed EAFs or small blast furnaces. Further scaleup, if successful, could enable Hismelt to replace small- to medium-size blast furnaces. The effect on flux consumption, however, would be minimal because fluxes currently used in sintering and pelletizing would then be charged directly into the Hismelt or other smelting-reduction vessels to obtain satisfactory slag chemistry.

Fines-Based Direct Reduction Processes

Included here are both fluidized bed processes using natural gas as a reductant and RHF processes using coal as a reductant. The latter are viable only if liquid iron or a pig-iron nugget can be produced or if only waste oxides are processed. The former include the Finmet process and its predecessor, the Fior process, in which iron ore fines are reduced in series of fluidized beds; the reduced fines are then hot-briquetted for subsequent shipment to mainly EAF steel-making furnaces. No binders or fluxes are used. Two commercial

plants have been built with a total capacity approaching 4 Mtpy. The capital costs at such plants are very high, and it is possible that no additional plants will be built.

FUTURE OF SINTERING AND PELLETIZING

The future of sintering and pelletizing is directly related to the future of those ironmaking processes that use sinter and pellets, mainly the blast furnace and the shaft furnace DR processes. The future of these processes in turn depends on worldwide steel production and consumption, which have been on an upward trend for the past century, with some important interruptions for events such as the Great Depression, the oil shocks, the fall of the Soviet Union, and the Asian financial crisis. Currently, global steel production is again on an upward trend, led by explosive growth in China, most of which is based on the blast furnace process. This growth has led to very strong demand for both pellets and sintering ore. Steel production in the rest of the world is expected to be reasonably stable through this decade. Some continual but gradual shifting toward EAF-based steelmaking at the expense of BF/BOF steelmaking will occur in North America and Western Europe. This will reduce sintering capacity in these regions, but global growth, mainly in China, will present an overall increase in sintering capacity. Worldwide pellet capacity will continue to grow to feed both blast furnace based expansions and DR/EAF based expansions, mainly in regions rich in natural gas, such as the Middle East.

Government, Environment, and Health Considerations

Globally, governments view steel production favorably because of the economic importance of the steel industry. Government attitudes about public ownership have shifted in favor of private investment, both locally and globally. The privatization trend has led to increased investment, improved energy efficiency, and planned growth. Growth in the steel industry has had a corresponding growth in agglomeration practice, whereas the use of uneconomic local lump ores continues to decline. The practice of producing sinter on-site has increased and is based on rich iron ores and pellets from local or seaborne sources, but mainly from seaborne trade. In North America, government actions concerning international trade have been favorable, but environmental mandates, currency appreciation, and tax and labor policies have presented challenges to the BF/BOF sector in particular. This has sharply reduced sintering capacity and led to consolidation of pellet plant capacity.

The sintering process in particular has been challenged by environmental interests. Worldwide, steel companies have made major capital investments to install or upgrade flue-gas scrubbing systems in sinter plants. For most of the world, sintering is the key iron-bearing feed preparation process, so these investments have been justified; steel companies, however, continue to face pressure on the issue of dioxin releases from sinter plants. Considerable technological progress has been made in this area in recent years, and it is now believed that the dioxin issue will not lead to widespread sinter plant shutdowns as originally feared. In North America, where relatively modern pellet plant capacity was available, steel companies shut down many smaller, older sinter plants that would have required significant capital spending to address these environmental concerns.

Most of the world's pelletizing capacity, including nearly all of that in North America, was built in the 1970s and 1980s with state-of-the-art equipment for air and water pollution control. Furthermore, most pelletizing capacity is at or near mine sites and

Table 11. Environmental emissions of agglomeration processes

Process	Emissions				
	SO ₂ , g/t	NO _x , g/t	CO, kg/t	CO ₂ , kg/t	Particulates, g/t
Sintering	1,670	640	38	220	260
Pelletizing, hematite ore	200	500	1	30	130
Pelletizing, magnetite ore	100	200	<1	25	125

Adapted from LKAB 2000.

typically in remote areas. By contrast, sinter plants are located within steel plants, which themselves are frequently located in or near densely populated urban areas. Accordingly, pellet plants have faced far less environmental pressure than have sinter plants. A portion of this is attributed to lower emissions, as indicated by the data in Table 11.

The differences shown in Table 11 arise mostly from fuel consumption. Magnetite ores have the lowest external fuel requirement due to the heat released when oxidizing magnetite to hematite at the start of the indurating process. Pelletizing hematite ores requires less fuel than sintering because of better heat utilization in the process. Hematite pellet producers use about 22 to 30 kg/t of coal or other carbonaceous fuels such as anthracite, coke breeze, or pet coke per ton of ore. Nearly all U.S. pellet plants process magnetite ores and Canadian pellet plants process mainly hematite ores. Worldwide, most of the pelletized ore is hematite, with some notable exceptions such as Sweden.

The issue of CO₂ emissions and the Kyoto Accord is also a concern. Because blast furnace ironmaking/steelmaking is a major contributor of CO₂ emissions, a solution must be found to avoid large-scale deindustrialization in developed countries. In the interim, the steel industry and iron ore pelletizing companies are demonstrating their commitment to minimizing CO₂ emissions, mainly by striving to minimize overall energy consumption.

Fluxes for Metallurgy

Harold R. Kokal

INTRODUCTION

Although the use of fluxes in metallurgy spans the globe, this chapter is limited to include uses, consumption, and operations in the United States. The principles described, however, are universal in nature. Information on world sources, specific transportation issues, supply and demand, and marketing in foreign countries can be found in other chapters of this book, references in libraries, and, more recently, on the Internet (USGS 2004). Previous editions of *Industrial Minerals and Rocks* can be reviewed for an historical perspective on the industry (Boynton and Gutschick 1960, 1975; Gillson et al. 1960; Severinghaus 1960; Lawrence 1975).

The consumption of limestone, dolomite, and silica as metallurgical fluxes is small compared to the total consumption of crushed stone. Only about 10% of total consumption is used in the chemical and metallurgical industries, and only about 10% of that is used as flux (Tepordei 2002a). Therefore, the industrial use of fluxes is a specialized niche comprising only about 1% of total production within the much larger crushed stone industry. This chapter concentrates on flux uses in the iron and steel industry, because about 90% of all metal consumed in the United States and in the world is iron and steel (Habashi 1986; USBM 1991). The use of flux for processing several nonferrous metals is discussed only briefly.

This chapter is restricted to the uses of flux minerals in thermal processes; fluxing minerals as neutralizing agents in the hydrometallurgical processes and other chemical processes are not discussed. The latter subjects are covered elsewhere in this book. Also, the use of fluxes in welding and brazing is not discussed here, but the subject is covered well by Lawrence (1975) and in other chapters of this book.

THE CONCEPT OF FLUXES

A metallurgical flux is a substance that is combined with gangue (unwanted minerals) in ores during smelting, with impurities in a molten metal, or with other additives in metal refining to form a slag that can be separated from the metal. Slags are immiscible with the metallic melt and are of lower density, so that a clean separation of slag and metal occurs when the proper conditions are attained. Slag chemistries are adjusted to provide the proper melting point, viscosity, surface tension, conductivity, specific heat, density, or chemical properties for the particular metallurgical process. In addition to absorbing impurities from the metal, slag thermally

insulates the metal bath, protects the molten metal from the atmosphere, and controls the chemical potential of the system. Several excellent references on slags and metallurgical fluxes are available (Rosenqvist 1974; Boynton 1980; Turkdogan 1983; Fine and Gaskell 1984; Lankford et al. 1985).

Fluxes often are selected to make slags that perform different functions at different stages of a process prior to final melting. For example, slag composition and behavior will change as materials descend in the iron blast furnace and as materials melt in the early stages during steelmaking. Selection of slag chemistry might be influenced by factors other than their primary function; for example, blast furnace slags might be used to make cement, rock wool insulation, or aggregate. In some cases, steelmaking slags containing sufficiently high phosphorus content have been marketed as fertilizers. Slags containing sufficient quantities of valuable recoverable elements may be sold as raw materials for other processes. For example, during production of pig iron from titanium-rich ores by the Sorel process, a slag rich in titanium dioxide is made and used as a raw material for subsequent recovery of titanium metal (Knittel 1983). The U.S. Geological Survey (USGS) monitors slag as a separate mineral commodity (Kalyoncu 2001).

GENERAL USES OF FLUXES

The production of carbon steel of many types is accomplished by the reduction and smelting of iron-bearing materials (pellets, sinter, and lump ore) and fluxes in blast furnaces with subsequent refining of molten iron and scrap in oxygen-blown furnaces. Some carbon steels, as well as stainless steels, ferroalloys, and special alloys, are made in electric-arc furnaces. Limestone and lime are the major fluxes used in ironmaking and steelmaking, but dolomite, dolomitic lime, silica, alumina, and fluorspar also are used. Foundry cupolas also employ some limestone and dolomite (Boynton 1980), and small amounts of limestone and lime are used in nonferrous metallurgy.

In blast furnace ironmaking, the flux is added either by direct charging of sized lumps or through sinter and fluxed pellets. Silica and alumina sometimes are added to blast furnaces either by direct charging of sized lumps or through sinter. During steel refining in either oxygen-blown furnaces or electric-arc furnaces (EAFs), flux is added as lime and dolomitic lime either charged as lumps or injected as fines; sometimes a small amount of limestone is used. Occasionally, fluorspar is added as lumps or mixed with other fine materials in briquettes. During refining in ladles prior to casting

steel, special slags are made with compositions optimized for removal of impurities. In continuous casting, additional specialized fluxes are added.

Flux minerals sometimes are added to repair refractories. In the basic oxygen process for steelmaking, lime from the flux combines with silica (formed by oxidation of silicon from the metal) to form a slag. This slag will attack the magnesia refractory brick that lines the steelmaking vessel, so magnesia (MgO in some form) is added to help prevent damage to the refractory (Boynton 1980; Lankford et al. 1985). The selection of a flux material to repair the refractory lining of smelting and refining vessels depends on the type of refractory and the process itself. In copper smelting, an acid slag practice is used, and silica is added for repair of refractories in the smelting furnaces (Anderson 1961; Fowler 1961).

Fluxes contained in a slag that formed in one operation can also serve as flux in another. Slags that formed in refining operations often are recycled to smelting operations to provide flux materials and to recover elements that otherwise might be lost. For example, steelmaking slags are recycled to the blast furnace to recover unreacted, precalcined lime, and iron and manganese oxides. Impurities, particularly sulfur, phosphorus, and zinc, limit the recycling of steelmaking slag to the iron blast furnace. In copper smelting, converter slags are recycled to recover copper and flux; however, the extent of recycling depends on the level of impurities such as bismuth, antimony, and arsenic.

TYPES OF FLUXES

Fluxes often are referred to as *acid*, *basic*, or *neutral*. Acid fluxes are those that form acids in water, and basic fluxes form bases in water. Typical acid fluxes are silica, alumina, and phosphorus, although alumina may function as either an acid or base. Typical basic fluxes are lime and magnesia. Fluorspar, or calcium fluoride, is considered a neutral substance because it is viewed as the reaction product of a base and an acid. The degree of acidity (ratio of acids to bases) or basicity (ratio of bases to acids) often is specified to characterize slag chemistry for a particular system, which in turn might be referred to as acid or basic depending on the type of slag. For example, steelmaking is basic because it uses slags with more bases (lime and magnesia) than acids (silica and alumina).

The choice of minerals and compounds used as fluxes depends on the requirements of the process, availability, costs, requirements for recycling of intermediate products, and environmental concerns. Because slags are most often mixtures of oxides and silicates, fluxes are usually oxides, carbonates (which decompose to oxides), and silicates. Slags containing phosphates, borates, sulfides, carbides, or halides also have been used (Rosenqvist 1974; Moore 1981; Szekely, Carlsson, and Helle 1989). In ironmaking and steelmaking, slags are basic, so the primary flux is lime-bearing, although acidic components also may be added. In nonferrous processes, slags and fluxes are generally acidic (silica is the primary component), although small amounts of basic fluxes such as limestone or lime are used to modify slag properties, and some nonferrous refining slags are lime based.

Typical acid fluxes are siliceous sand and gravel, quartz rock, used silica brick, or raw siliceous ore (Lankford et al. 1985). Olivine, a magnesium-silicate mineral, has been added to iron blast furnaces to enhance removal of alkalis. Alumina-based fluxes include bauxite, aluminiferous clay, and recycled alumina brick. Alumina can function amphoterically, forming either aluminum silicate in high-silica slags or calcium aluminate in lime-bearing slags (Lankford et al. 1985).

The principal basic fluxes are limestone (calcium carbonate) and dolomite (calcium–magnesium carbonate), sometimes called

fluxstones (Boynton 1980), and their calcined forms, lime and dolomitic lime. The advantages of externally calcined fluxes are that they require less expensive forms of energy to effect decomposition than when they are used in the blast furnace (e.g., where coke is the main fuel), and they cause less boiling in steelmaking vessels because carbon dioxide gas is already removed. Limestone and dolomite are considerably less expensive than lime and dolomitic lime. The calcined forms are more difficult to handle and are highly reactive with water. Dolomite and dolomitic lime are used for their magnesia contents.

Fluorspar is a neutral flux once used widely in steelmaking slags to improve fluidity and also has been used together with lime as a primary slag in electroslag refining (Duckworth and Hoyle 1969). The lowest grade of fluorspar (metallurgical spar) often is used for steelmaking. When the price of fluorspar is high, substitutes, including aluminum smelting dross, borax, manganese ore, titania, iron oxides, silica sand, and calcium chloride, may be used (Peters 1982). Briquettes with various combinations of low-grade manganese ore fines, mill scale, precipitator dust, recycled slag, and fine fluorspar have been used as flux in steelmaking to form a fluid slag. Over the last decade, the use of fluorspar in the steel industry has been decreasing.

Fluorspar is employed widely in the manufacture of aluminum. High-grade fluorspar (acid-grade fluorspar used to make hydrofluoric acid) is used to make cryolite (AlF_3), which, along with fluorspar, is used in a molten bath to dissolve alumina and recover electrolytic aluminum (Miller 2002a).

Since about 1980, iron- and steelmakers have been using synthetic slags for external treatment of hot metal from the blast furnaces and for treatment of steel in ladles subsequent to basic oxygen furnace (BOF) and EAF processing. These treatments include flux additions for removal of silicon, sulfur, and phosphorus. Synthetic slags are made by adding magnesium or aluminum metal, magnesium–aluminum or calcium–silicon alloys, calcium carbide, prefused calcium aluminate, and mixtures of some of these to coke, lime, and fluorspar (Stubbles 1984). Sodium carbonate (soda ash) can be used for desulfurization and dephosphorization of steel (Yamamoto, Kajioka, and Nakamura 1980; Szekely, Carlsson, and Helle 1989). Special synthetic compounds also are used as mold fluxes in the continuous casting of steel (Branion 1987). Additional applications include nonferrous metallurgy, the ferroalloy industries, and foundries (Szekely, Carlsson, and Helle 1989).

PRODUCTION, CONSUMPTION, AND PRICING Sources of Flux Materials

Deposits of limestone and dolomite are widespread and often are found near ironmaking centers. In the United States, limestone and dolomite fluxes presently used for ironmaking and steelmaking originate primarily from Michigan. Historically, these fluxstones were of the type and purity useful for ironmaking and could readily and economically be transported to iron- and steel-producing centers. Small amounts of fluxstone also are obtained in Alabama, Ohio, Pennsylvania, and Illinois (Lawrence 1975; Lankford et al. 1985).

Minor flux materials used in ironmaking and steelmaking include alumina, silica, and fluorspar. In the United States there is a shortage of high-grade, alumina resources except for aluminiferous clays, which contain silica. Because alumina and silica must be added independently, bauxite (a form of alumina-bearing ore) must be imported from Greece, Turkey, or Jamaica. In contrast, siliceous materials are plentiful. Typical silica resources for blast furnaces include raw ore from iron mines and local siliceous gravel. Local siliceous sands, olivine, and other fine siliceous materials

are used to increase the silica content of sinter. Fluorspar for steel-making is imported to the United States from China, South Africa, and Mexico.

In the nonferrous industries, fluxes are largely siliceous, and lean ores or other nearby rocks often are used as fluxes, providing that impurities are low. In some instances, high-grade silica rock is used. Gypsum, a sulfate of calcium, has been used as a source of lime and sulfur in nickel smelting (Habashi 1986).

Transportation

Long-distance transportation of limestone and dolomite is uncommon because of their low unit values and widespread occurrence; however, if high purity is required, higher-cost lime and dolomitic lime might be transported over greater distances in some special cases. For example, low-impurity flux has been transported from Japan to Australia to supplement local impure sources for use in fluxed pellets.

In the United States, limestone and dolomite are transported to the steel-producing centers by ship on the Great Lakes, by barge on rivers, and by railroad. Sinter plants are often located at or near steel mills to take advantage of the availability of a variety of iron-bearing raw materials, coke fines, and slag. Some steel producers operate their own lime plants to produce both high-calcium lime and dolomitic lime, while others purchase their lime from independent producers. Captive lime plants often are located near steelmaking operations and in some cases are connected by conveyor belts. In other situations, lime is transported by truck, barge, or rail. The USGS publishes a directory of lime plants (Miller 2004).

The trend toward using fluxed pellets in blast furnaces has required a change in the transportation and distribution patterns of limestone and dolomite. In the United States, fluxed pellets are not made near the steel mills but instead at the iron ore mines in Minnesota and Michigan, which are located farther from the steel mills than from the limestone and dolomite quarries. Therefore, the limestone and dolomite fluxes must be backhauled to the mines by boat and railroad before being returned to the steel mills in the form of fluxed pellets. In some instances, fluxed pellets made in Minnesota with flux from Michigan have been transported as far as Alabama and Utah by railroad.

End Users

The sizes of stone used for flux are generally less than 150 mm but greater than 150 mesh (0.104 mm). The coarsest sizes are used for direct charging to shaft-type lime kilns and blast furnaces; intermediate sizes are used for manufacture of lime in rotary kilns and direct charging to blast furnaces; and the finer sizes are used for sinter. There is some flexibility in stone size if appropriate facilities for crushing, grinding, and sizing are available. The intermediate to fine sizes are used for fluxed pellets after additional crushing and grinding. Sizes below 150 mesh (0.104 mm) often contain impurities detrimental to ironmaking and steelmaking, and are either sold for agricultural use or disposed of as waste (see the chapters on lime, agglomeration processes, and limestone and dolomite for more details). For discussions on fluxed pellets and sinter production, refer to the Agglomeration Processes chapter, as well as Ball et al. (1973).

Lime often is added to sinter mixes to promote microagglomeration of fines and to serve as a source of calcium, or, in the case of dolomitic lime, as a source of calcium and magnesium. Lime and hydrated lime also have been investigated as binders in iron ore pellets; however, this can result in cracked pellets after induration (firing) of pellets caused by rapid release of the water of hydration (Ramos 1999).

High-calcium lime and dolomitic lime used as fluxes in steel-making have specific particle size requirements. The sizes of stone required for lime burning are fairly well fixed and are adjusted to make the required particle sizes of lime. In the nonferrous industries, lime, in addition to smelting and refining, is used to treat acid wastes and to control acidity in flotation and cyanidation plants.

Factors Affecting Pricing

Limestone and Dolomite

The USGS publishes information on the production, consumption, and value of crushed stone, which includes the flux minerals limestone and dolomite (Tepordei 2002a). Major sources of fluxstone used in the ferrous and nonferrous industries are domestic. Trends in the production, consumption, and value of fluxstone (limestone and dolomite), used predominately in the iron and steel industry, are shown in Table 1. The quantity used in the iron and steel industry is about 1% of total crushed limestone and dolomite consumption.

The total of crushed stone reported as flux is only slightly greater than the amount reported as fluxstone; the difference can be attributed to materials other than limestone and dolomite. During the period from 1998 to 2002, the reported amount of fluxstone used by the iron and steel industry decreased from about 7 Mtpy to less than 2.5 Mtpy. This not only reflects the depression in steel production during that period, but it also most likely reflects consumption from stock piles and underreporting by companies that were consolidating. During the same period, the average value of fluxstone increased from \$4.29/t to \$5.14/t.

Quantities and values of limestone and dolomite used within the chemical and metallurgical industries, including uses for lime making and flux, are shown in Table 2. The consumption of limestone is greater than the consumption of dolomite as flux.

Lime

The USGS publishes data related to production and consumption of lime (Miller 2002b). Most lime is produced domestically (Miller 2004), and the iron and steel industry contributes about one-third of the total lime demand (Table 1, which also shows trends for the period from 1998 to 2002); the decline in usage reflects the depression in the steel industry. The price of lime gradually increased from about \$58/t in 1998 to \$60/t in 2002. In 1989, the value of metallurgical lime was between \$50/t and \$55/t. In 2004, prices spiked dramatically for many raw materials, and the price of lime was also much higher than in 2002 and 2003.

The consumption and value of lime in the metallurgical industries between 1998 and 2002 are shown in Table 3, which also shows the uses of lime in the BOF and the EAF steelmaking processes. In 2002, lime use in the nonferrous industries, excluding smelting and refining, was about 18% of that used in ironmaking and steelmaking. This percentage has decreased steadily from 1998 to 2002.

Fluorspar

Table 1 shows fluorspar production and consumption. About 20% of total fluorspar demand is for crude steel production (Miller 2002c), which decreased from 1998 to 2002, from about 600,000 tpy to 450,000 tpy. The price for metallurgical purposes held relatively constant at \$89/t. The small decrease in price in 2001 reflects the slump in the steel industry as well as possible stockpile sales.

INDUSTRY STRUCTURE

Infrastructure

During the past decade, the flux industry has undergone dynamic and even abrupt changes because of large-scale consolidation within the iron, steel, and copper industries. A smaller number of

more efficient, larger producers now exist. In order to concentrate on their core business, many iron and steel producers sold captive limestone and dolomite operations. Most limestone and dolomite flux used in the steel industry now is supplied by less than a half dozen large producers (often the flux is supplied from the same quarries). A directory of principal producers of crushed stone, including limestone and dolomite, is published annually (Tepordei 2002b).

Some flux applications have changed, altering patterns of use and quantities. For example, limestone and dolomite fluxes used in blast furnace ironmaking previously were added directly to the blast furnaces or as flux through the sinter process, but today they are added as precalcined fluxes through the use of fluxed pellets. There also has been a large growth in mini-mill steelmaking with EAFs that rely primarily on scrap and direct reduced iron as sources of iron. These sources contain less gangue, thereby requiring less flux than the conventional blast furnace process.

Imports/Exports

Very small amounts of limestone, dolomite, lime, and dolomitic lime are imported and exported; however, USGS does not report quantities specifically used for flux. A small amount of fluorspar is

exported, although almost none is produced domestically. Some imports or excess inventories may be sold and reported as exports.

CHARACTERISTICS OF FLUX RAW MATERIALS

Selection of flux for a particular process depends on the chemical specifications to form a slag of the required composition. Ideally, only pure substances would be selected; however, these are seldom available in nature. Impurities in the flux should be minimal. Large amounts of impurities render the flux less effective, therefore requiring larger amounts of flux. Some minor impurities can have significant detrimental effects on the process or equipment. Once the chemistry is specified, particle size of the flux is determined largely by handling and gas-flow requirements of a particular process and, to a lesser extent, by the particle size or size distribution of flux available. Geographic location and economics may dictate the selection of a flux with the desired chemical or physical specifications; otherwise a new source may be explored.

Chemistry of Limestone and Dolomite

Limestone (CaCO_3) and dolomite ($(\text{Ca,Mg})\text{CO}_3$) are used in smelting iron ores to supply lime (CaO) and magnesia (MgO), respectively, to form a slag with acid components silica (SiO_2) and alumina (Al_2O_3). Table 4 gives typical chemical analyses for limestone, dolomite, and their respective calcined products. The ideal flux is low in acids (silica, alumina, and sometimes titania [TiO_2] and iron oxide), sulfur (S), phosphorus (P), alkali metals (sodium and potassium), and halides (chlorides and fluorides). All phosphorus in ironmaking raw materials, including iron ores or agglomerates, coke, and fluxstone, is reduced to the elemental state in the blast furnace and appears in the iron product; therefore, phosphorus must be minimized in the flux. This is particularly true with recycled slags, and it is the phosphorus content that often determines the amount of steelmaking slag that can be recycled to ironmaking. Because a major purpose of the ironmaking slag is to remove sulfur, sulfur in flux as well as other materials should be low. Alkali

metals are generally detrimental to the blast furnace operation, often forming deposits on the furnace walls; therefore, alkali inputs from raw materials should be minimized. During the production of fluxed pellets or sinter, the alkali metals, in combination with sulfur, chlorides, and fluorides, have been found to be extremely detrimental to some process equipment.

Adding silica to the blast furnace often is required to attain the proper ratio of basic to acid components in the slag. In traditional blast furnace practice, up to 5% silica in the flux was tolerated and 1% to 3% was common (Gault and Ames 1960). Today, silica levels are generally lower and the amount tolerated depends on whether the flux is used for making sinter or for direct charging; the levels of silica in other burden materials is also a factor. The allowable silica level also depends on the required slag chemistry, the volume of slag required for control of the furnace, and the amount of sulfur and alkali metals present.

The MgO content of limestone added to the blast furnace is often not critical. The amount tolerated depends on the MgO content

of all burden materials and the target slag chemistry. Higher MgO content keeps the slag fluid over a wider temperature range (Gault and Ames 1960; Rosenqvist 1974). Dolomite may be added to provide sufficient MgO to produce slag to meet a certain by-product specification, for example, slag for use as aggregate. MgO added in sufficient amounts increases the melting point, and this effect is used to advantage when making fluxed pellets for the blast furnace. The MgO content of limestone must be known when producing blends of limestone and dolomite for use in fluxed agglomerates.

Physical Properties of Limestone and Dolomite

Traditional ironmaking relied on direct charging of the iron blast furnace with flux materials up to 150 mm in size. Today the need for a uniformly sized and permeable burden requires that the size be more compatible with other burden materials; therefore, stone as fine as 50 × 12.5 mm has been used. By changing the size of stone, the location in the blast furnace where complete calcination occurs can be regulated (Lankford et al. 1985). Typically, flux added to

† Ball mill grinding.

sinter is in the range of –6.35 to –3.17 mm in size with 90% coarser than 150 mesh (0.104 mm). Some iron producers have adopted the use of fluxed pellets, which requires that the stone be ground to 60% to 80% passing 200 mesh (0.074 mm), a size more compatible with the formation of pellets from fine concentrates. Table 5 shows the size ranges of limestone and dolomite required for the blast furnace, lime plant, sinter plant, and fluxed pellet plant.

Thermal decrepitation and physical degradation of fluxstone are undesirable because the presence of fines reduces the permeability of the furnace burden. Experience has shown that fine-grained stone decrepitates less than coarse-grained stone in the blast furnace (Gault and Ames 1960). Resistance of stone to physical degradation during handling and transportation is also important in minimizing the amount of fines formed. If fines are deleterious to the process, they must be removed by screening. If fines have no alternate use, the cost of the flux is effectively increased.

Chemical Properties of Lime

Prior to use in steelmaking, limestone and dolomite are calcined or heated to drive off carbon dioxide. In the blast furnace, calcination of limestone begins at temperatures higher than 800°C and dolomite typically begins dissociating at about 700°C (Ricketts 1992).

Typical analyses of lime and dolomitic lime are shown in Table 4. In steelmaking, high-calcium lime with low silica content is specified because lime combines with silica formed by oxidation of silicon in the steel bath. Dolomitic lime is added in steelmaking

to control the MgO content in order to minimize wear of the basic refractory lining.

The available base (*AB*) for reaction with acidic components is important (Peters 1982; Lankford et al. 1985). The *AB* is calculated in either of two ways:

$$AB = \text{CaO}/(\text{SiO}_2 + \text{R}_2\text{O}_3),$$

$$\text{or } AB = \text{CaO} + \text{MgO} - \text{SiO}_2 - \text{R}_2\text{O}_3 - LOI,$$

where

R_2O_3 = the sum of the Fe_2O_3 , Al_2O_3 , Cr_2O_3 , and TiO_2 ;

LOI = loss on ignition.

The sulfur content of lime should be low, because absorption of sulfur that originates from either stone or fuel (or both) during calcining can be a major problem. The sulfur level in lime can be controlled by regulating oxygen content in the calcining system exit gas. Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) in fluxstone is undesirable because it is difficult to dissociate, but generally sulfur in pyrite (FeS_2) or pyrrhotite (Fe_{1-x}S , where $x = 0-0.2$) can be removed. Sulfur also occurs as organic sulfur in the stone. Sulfur levels of 0.03 % to 0.06% in the lime are typical.

After calcining, lime is hygroscopic and slakes to form calcium hydroxide. In addition, some uptake of carbon dioxide and sulfur dioxide can occur, forming a dense layer of calcium carbonate and/or gypsum on the surface. This layer can adversely affect the subsequent reaction rate of the lime. If lime is not completely calcined, a

core of unreacted limestone (or dolomite) will remain. Unreacted core, along with adsorbed water and carbon dioxide, will result in LOI when the lime is heated. Lime for steelmaking generally requires a low value LOI of 2% to 4% (or less); some plants actually require an LOI no higher than 0.5% (Boynton 1980).

Physical Properties of Lime

The particle size of lime used in steelmaking is typically 37 mm by 6.35 mm. Particle size is important because if sizes are too fine, the intense gas flow above the steelmaking vessel can remove them before the lime reacts to form slag. Typically, particles <3 mm in size are removed. Although considerable effort is made to minimize the creation of fines in the lime, degradation occurs during hydration and carbonation in storage and through physical handling. Lime placed in storage might contain between 5% and 20% fines less than 3 mm in size; however, after several days in storage, fully one third can degrade further, and up to one half will exist as fines that result from handling and transfers before use in steelmaking.

Several steelmaking processes use bottom blowing, and some use combined top and bottom blowing so that much finer flux can be used if injected. Fine lime can be pneumatically conveyed by oxygen or a carrier gas and injected through tuyeres (openings) in the vessel bottom. The high surface area of lime fines promotes rapid slag-metal reactions. The size of lime particles typically used in the injection process is about the same as (or finer than) those shown for pellet flux in Table 5 (Koros, Petrushka, and George 1991).

Requirements for Fluorspar

Fluorspar or calcium fluoride (CaF_2) sometimes is used as a flux along with lime to improve the fluidity of slag in steelmaking and subsequent ladle metallurgy processing. Typical consumption of fluorspar in steelmaking is 2 to 10 kg/t or 5% to 10% of the lime added (Peters 1982). In electroslag refining, fluorspar is used in a ratio of about 70 parts fluorspar to 30 parts lime (Duckworth and Hoyle 1969). The purpose in electroslag refining is to form a very conductive slag with the required melting point. In aluminum smelting, about 23 kg fluoride as AlF_3 equivalent is used per ton of aluminum (Miller 2002b).

The specification for metallurgical-grade fluorspar is 72% minimum effective fluorspar, where the effective fluorspar is calculated as follows:

$$\text{Effective CaF}_2 = \text{CaF}_2 - (2.5 \times \text{SiO}_2)$$

The major impurity in fluorspar is silica; the balance of impurities includes calcium carbonate and small amounts of barite (BaSO_4), lead, and zinc. Table 6 shows chemical analyses of typical fluorspars.

Fluorspar can be added as lumps, gravel-sized material, or fines incorporated in briquettes. Sizes of gravel and screen fines are shown in the footnotes to Table 6. Typically, 5% to 15% fluorspar fines are added to briquettes made with recycled slag fines or other steelmaking ingredients. The latter is often preferred to achieve better mixing of fluxes and better reaction with the slag. Any loose fines will be lost during the blow.

Other Materials

Silica-bearing materials sometimes are added to the blast furnace to control the basicity of the process and to counteract overaddition of basic fluxes, although additions are kept to a minimum. The chemistry of the material should be compatible with the process, and deleterious elements such as alkali metals, phosphorus, and sulfur are avoided. In ironmaking, typical silica sources are low-grade taconite ore, flint clay containing alumina, sandstone, siliceous gravel, or

Table 6. Composition of metallurgical-grade fluorspar (dry basis), wt %

‡ Oxides of iron and aluminum and sulfur can sometimes reach 1% in lower-grade products.

used brick. If the added material is low grade with respect to silica, a larger, measurable, and more controllable quantity can be used. For example, addition of taconite ore containing 50% silica and 35% iron allows extra iron units to be added to the furnace while providing a larger volume of material than if using pure silica. In copper smelting, low-grade ores or rock and sometimes high-grade silica are used. In any process, the size of the flux material should be compatible with the process: fine enough to react rapidly but not so fine as to cause permeability problems or to be lost as dust.

Testing Procedures

Many standard tests for characterizing lime and limestone (as well as dolomitic lime, dolomite, fluorspar, and other materials) have been developed by the American Society for Testing and Materials (ASTM) (ASTM 2003a, 2003b, 2003c). The ASTM tests commonly applied are listed in Table 7. Accurate sampling of stone is often a problem because of its large size or wide range of sizes. Sampling of lime and fluxstone is described in ASTM tests C-50 and D-75. Chemical analysis of limestone and dolomite is accomplished easily according to standard procedures defined in ASTM C-25 and C-1301 and by published or proprietary methods using modern analytical techniques. Methods for analysis of fluorspar are given in E-463 and E-815 (ASTM 1989). Physical testing is defined in ASTM C-110. The physical test most often done is sizing or screening of stone to determine size distribution described in ASTM E-11, C-136, E-276, and E-389. Degradation characteristics can be determined by the Los Angeles abrasion test for fine or coarse aggregates (ASTM C-131 and ASTM C-535). A drop test, approximating heights at which stone will be conveyed, is used to estimate amounts of degradation during handling and transportation (Fagerberg and Sandberg 1974).

The ASTM water reactivity test, ASTM C-110, is often used to test lime reactivity for steelmaking (Schlitt and Healy 1970). The American Water Works Association Standard B202-02 is similar. Although there is some correlation of water reactivity with slag formation, a crucible test is probably more directly related to lime behavior in steelmaking (Limes and Russel 1970).

TECHNOLOGY

Successful application of a particular slag in a metallurgical process depends on its chemistry and properties when molten, which are controlled by the selection of appropriate fluxes. Important properties of a slag are: melting point, viscosity, surface tension, density, and chemical activities of its components. In electro-slag smelting, conductivity also is important. The effects of composition on melting temperature in relation to its other properties often are

Table 7. ASTM standard physical and chemical tests and definitions applicable to limestone, dolomite, and fluorspar*

ASTM No.	Description
C 25-99	Chemical Analysis of Limestone, Quicklime, and Hydrated Lime
C 29/C29M-97(2003)	Bulk Density (Unit Weight) and Voids in Aggregate
C 50-00	Sampling, Sample Preparation, Packing and Marking of Lime and Limestone Products
C 51-05	Standard Terminology Relating to Lime and Limestone as Used by the Industry
C 70-94(2001)	Surface Moisture in Fine Aggregate
C 110-05	Physical Testing of Quicklime, Hydrated Lime, and Limestone
C117-04	Standard Test Method for Materials Finer than 75 μm (No. 200) Sieve in Mineral Aggregates by Washing
C 125-03	Definition of Terms Relating to Concrete and Concrete Aggregates
C 127-04	Density, Relative Density (Specific Gravity) and Absorption of Coarse Aggregate
C 128-04a	Density, Relative Density (Specific Gravity) and Absorption of Fine Aggregate

described by temperature–composition diagrams (phase diagrams) and property–composition diagrams. It is convenient practice to use index values to describe composition requirements of a given process. Thorough discussions of the properties of metallurgical slags can be found in several references (Derge and Tenenbaum 1951; Rosenqvist 1974; Turkdogan 1983; Elliott 1984; Lankford et al. 1985; Mills and Keene 1987).

Properties of Slags

Melting Point

The melting point of pure lime is higher than process temperatures during smelting of iron ores or refining of steel; however, when lime is added to other components, such as silica, the melting point is lowered and a liquid phase forms. This phenomenon also is used in multicomponent systems. In most systems, there typically are more than two components, and interactions between components become complex. It is customary to represent these complex interactions on ternary, or 3-component, composition diagrams. Phase diagrams for many systems, including those in ironmaking, steelmaking, and nonferrous smelting and refining, can be found in a series of publications: *Phase Diagrams for Ceramists* (Levin et al. 1956–1969) or *Phase Equilibria among Oxides in Steelmaking* (Muan and Osborn 1965).

Iron blast furnace slags are represented in a $\text{CaO}\cdot\text{SiO}_2\cdot\text{Al}_2\text{O}_3$ ternary system. Typical iron blast furnace slag contains 32% to 42% SiO_2 ; 7% to 16% Al_2O_3 ; 32% to 45% calcia (CaO); and 5% to 15% MgO (Lankford et al. 1985). Slag compositions vary significantly from one country to another depending on the chemistries of the raw materials available (Blattner 1992).

Iron blast furnace slag is controlled to maintain a composition with about 10% Al_2O_3 (some practices contain greater amounts) to achieve a relatively constant melting point and to maintain slag liquid over a wide range of lime and silica combinations. The melting point is typically 1,400°C to 1,500°C. Ferrous iron reacts with silica at much lower temperatures than calcia and alumina, and local melting can occur in the lower part of an iron blast furnace shaft. One purpose of flux in fluxed pellets is to avoid early melting that results from the formation of iron silicate (Fe_2SiO_4 or fayalite) by preferentially reacting silica in the pellets with lime and magnesia (Taguchi, Hanaoka, and Ikeda 1980; Ranade 1992). In nonferrous smelting, iron silicate slags, which melt near 1,200°C, are formed.

Viscosity

Silica can form complex silicate networks in the molten state. These networks comprise chains of silica molecules that result in very viscous flow conditions. Because silica also melts at a high

temperature, separation and movement of silica is difficult. The addition of high-calcium lime breaks up the silicate networks, lowers the melting point, and decreases viscosity of the slag. Addition of the basic oxide magnesia has only a small effect on viscosity and is used to minimize the variability of viscosity over a range of slag compositions; however, if sufficient lime is present to precipitate dicalcium silicate (a solid phase), viscosity will increase rapidly (Rosenqvist 1974).

In steelmaking slags, lime is added as a flux to react with silicon and phosphorus oxidized from the steel bath. The reaction of lime is sometimes impeded by the formation of a dicalcium silicate or calcium ferrite coating on lime particles. Fluorspar is added to the steelmaking vessel to aid in dissolution of lime and to reduce the viscosity of the slag. Although the precise mechanism is not known, it is thought that fluorspar attacks the coatings on the lime (Peters 1982). Fluorspar melts at 1,386°C and dicalcium silicate melts at temperatures higher than 2,000°C, but when approximately equal portions of fluorspar and dicalcium silicate are mixed, the melting point decreases to lower than 1,200°C (Levin et al. 1956–1969).

Surface Tension

Although surface tension of slag is important, it is not used often to characterize slag because of the difficulty in measuring it. Surface tension affects the wetting of both metals and refractories by slags, and this in turn affects rates at which various components dissolve in the slag and the ease of separation of slag and metal. Foaming during blowing in basic oxygen steelmaking, and also in the EAF, is affected by surface tension. Surface tension decreases with increasing silica content, with the addition of alkali oxides, calcium sulfide, and phosphoric oxide, and with an increase in temperature. Lime, iron oxide, and alumina increase the surface tension of slag (Rosenqvist 1974).

Density

Density is controlled to achieve separation of metal and slag by adjusting the proportions of components. In ironmaking, the slag density increases with increasing lime and iron contents, but it is not controlled specifically. In copper smelting, where the product is a matte with a density lower than the metal, the separation of slag and matte is enhanced by decreasing the density of the iron-rich slag by the addition of lime (Rosenqvist 1974).

Activity

The activity of a chemical species in a slag is a function of both concentration and temperature. It also determines how a particular chemical species will react with other components in a given system. Values of thermodynamic activity can predict the equilibrium in the process. Activity (a_i) is related to the more familiar concentration term expressed as the mole fraction (X_i) through the activity coefficient (g_i) by:

$$a_i = g_i \cdot X_i$$

For ideal gases, the activity is the partial pressure (p_i).

A thorough discussion on the thermodynamics of slag can be found in Derge and Tenenbaum (1951), Turkdogan (1983), Elliott (1984), Coudurier, Hopkins, and Wilkormirsky (1985), and Lankford et al. (1985). In general, activity cannot be predicted and must be measured experimentally, or the activity coefficient is predicted from slag models. Values for particular systems can be found in the previous references.

Sulfide Capacity

Slags desulfurize metals by reacting sulfur with lime to form calcium sulfide, which dissolves in the slag. The ability of slag to dissolve sulfides is expressed as the sulfide capacity (C_s), which is:

$$C_s = (\%S)(p_{O_2}/p_{S_2})^{1/2}$$

where

p_i = the partial pressure of component i (e.g., O_2 is oxygen, S_2 is sulfur).

Sulfide capacity can be expressed in terms of optical basicity (B_{OB} ; see definition in next section) and temperature as follows:

$$\log C_s = [(22690 - 54640 B_{OB})/T] + (43.6 B_{OB}) - 25.2$$

where

T = the temperature in degrees Kelvin (K) over the range 1,400° to 1,700°C (Sosinsky and Sommerville 1986).

The sulfide capacity of a slag increases with added amounts of lime, and a low silica activity (a_{SiO_2}) is desirable.

Index Values

The desired composition of a slag in a metallurgical system often is defined by index values that express the acidity, basicity, or the capacity of a slag to perform a desired function. The composition of slag is adjusted so that the flux will combine with impurities and gangue to yield a desired index value. Common index values are basicity (B) or total basicity (B_T), V-ratio, and B_{OB} .

Basicity

Basicity is the ratio of basic oxide components to acid oxide components in the slag and is defined in several ways. Because lime and silica are the most prevalent species in basic slags, the definition of basicity is often given as the lime-to-silica ratio or binary basicity (B_2):

$$B_2 = CaO/SiO_2$$

where the weight percent of the chemical species is used to compute the ratio. This ratio also is called the C/S ratio (using the first initials of CaO and SiO_2) in the manufacture of fluxed pellets. The magnesia-to-silica ratio (M/S ratio) also may be specified for fluxed pellets.

The most often-used definition of basicity in blast furnace practice is the four-component basicity (B_4), or total basicity, defined as:

$$B_T = B_4 = (CaO + MgO)/(SiO_2 + Al_2O_3)$$

Total basicity sometimes is modified to include titanium or phosphorus (P_2O_5) as acids.

V-Ratio

In steelmaking, the basicity often is referred to as the *V-ratio*, which expresses the ability of a slag to desulfurize or dephosphorize the steel. The V-ratio usually is defined as one of the following:

$$V\text{-ratio} = CaO/SiO_2$$

$$V\text{-ratio} = (CaO + MgO)/SiO_2$$

$$V\text{-ratio} = (CaO - 4P_2O_5)/SiO_2$$

Sometimes the V-ratio is synonymous with total basicity.

Optical Basicity

Optical basicity is used sometimes to characterize a slag for correlation with desulfurization (Sosinsky and Sommerville 1986;

Blattner 1992). The optical basicity is defined as follows (all quantities in wt %):

$$B_{OB} = (\text{CaO} + 1.11 \text{ MgO} + 0.915 \text{ SiO}_2 + 1.03 \text{ Al}_2\text{O}_3) / (\text{CaO} + 1.42 \text{ MgO} + 1.910 \text{ SiO}_2 + 1.69 \text{ Al}_2\text{O}_3)$$

USES OF FLUXES

Ferrous Metallurgy

Fluxes are used at various stages in the production of iron and steel. Iron used for steel production traditionally is produced in the iron blast furnace as described by Lankford et al. (1985). Studies of iron-bearing raw materials and dissections of iron blast furnace burdens have improved the high-temperature performance of the iron-bearing burdens (Taguchi, Hanaoka, and Ikeda 1980; Yamooka et al. 1980). This led to modifications in fluxing practices wherein flux was introduced to the furnaces as fluxed sinter and fluxed pellets rather than by direct charging. Another result was an increase in the use of external desulfurization of hot metal prior to steelmaking that allows greater flexibility in selection of furnace burden materials with respect to sulfur content and greater flexibility in furnace operations for controlling other furnace parameters (Stubbles 1984).

Steelmaking is accomplished in BOFs and EAFs. Modern steelmaking includes the treatment of steel in ladles for improved cleanliness, greater throughput in the steelmaking vessels, and shape control of inclusions in the continuous casting process, which now dominates over ingot processing (Szekely, Carlsson, and Helle 1989). A variety of powder mixtures and prefused slags are used as molten fluxes in the continuous casting of steel (Branion 1987).

Iron Blast Furnace

The modern iron blast furnace uses iron-bearing agglomerates, coke, and flux to produce hot metal. Flux, which is largely limestone and dolomite, provides basic compounds (calcium oxide and magnesium oxide) to the furnace charge to form slag with acid flux compounds (silicon oxide and aluminum oxide) present in the iron-bearing agglomerates and coke. Slag provides a medium to remove silica and alumina gangue (introduced with the ore and coke) and sulfur (introduced with the coke). To reduce impurity levels, hot metal produced from blast furnaces is treated further in transport vessels and in subsequent steelmaking operations, which also require the formation of slag.

Limestone and dolomite flux used in the blast furnace is added as 25- to 75-mm-sized lumps or is added to iron-bearing agglomerates and charged to the furnaces as fluxed pellets or fluxed sinter. Agglomerates are large particles formed from smaller ones, which are either fused at high temperatures or bonded at low temperatures to form material that is handled easily and transported with minimal degradation. Limestone and dolomite are proportioned to the silica and alumina in the agglomerates; the ratio is expressed as the basicity. For fluxed pellets, basicity is calculated as the C/S and M/S ratios, which reflect only the major components. A comprehensive overview of raw materials used in blast furnaces was published by Ranade (1992).

To achieve a fluid slag with adequate capacity to remove sulfides, total basicity (or four-component basicity) of iron blast furnace slags is typically between 1.05 and 1.15, although ratios as low as 0.9 and as high as 1.4 are reported (AISI 1989). Typically, fluxed pellet basicities are between 0.7 and 1.7, and sinter basicities are between 1.7 and 4.0. When the basicity of agglomerates is higher than the basicity of the furnace, siliceous materials are added to match the required furnace slag basicity. Coke ash furnishes silica to the furnace, but an additional siliceous material may be required.

Basicity of agglomerates is selected for specific reducing and melting properties that improve furnace operation. Higher basicities are necessary for sinter when its primary function is to provide calcined flux to the furnace. Melting of the sinter because of very high basicities can be a problem when dicalcium silicate forms.

With the emphasis on consistent quality, lower-cost hot metal, and high productivity from blast furnaces, improvements have been made in the type of burden and in the characteristics of agglomerates. To minimize heat loss during slag removal from the furnaces (which requires the burning of expensive coke), the trend is to lower slag volumes (actually, slag mass per unit of hot metal produced). Lower slag volumes are a result of using agglomerates with low amounts of gangue and using low ash coke, thereby decreasing limestone and dolomite consumption. Slag removal cannot be independently controlled, because slag is removed with the hot metal during tapping; other factors such as furnace size and design can affect slag volumes. There are also some economic tradeoffs; for example, less expensive high-sulfur coals may be available for making coke, which may offset the cost of using more flux.

The amount of flux charged directly to blast furnaces varies widely depending on amounts charged in fluxed agglomerates. The majority of blast furnaces in the United States operating with fluxed pellets and/or fluxed sinter require an additional amount of flux of 10 to 50 kg/t of hot metal. Those not using any fluxed burden materials are charging 100 to 250 kg/t (AISI 1989). Typically, 225 to 275 kg/t is normal, but many modern furnaces approach 200 kg/t. Some furnaces have reached 150 kg/t under special circumstances, while some are much higher (AISI 1989; Blattner 1992). With increased use of external desulfurization (described in the next section), lowering flux levels become a function of furnace operation. A typical blast furnace skip charge, for example, could contain 900 kg of pellets, 650 kg of fluxed sinter, 25 to 100 kg of recycled steelmaking slag, and 50 kg of dolomite, depending on the chemistry of individual materials used (Lankford et al. 1985).

The presence of alkali metal oxides (e.g., sodium and potassium in particular) in the blast furnace can lead to operating problems such as coke degradation and the formation of scaffolds, or buildups, on furnace walls. Scaffolds can greatly reduce permeability, causing damage if they break loose. Alkali metal content in the furnace is regulated through the selection of raw materials and through the control of slag basicity (Sciulli 1992). Alkali removal is greatest with slags of low basicity; 60% to 80% of the alkali input is typically removed with the slag.

External Treatment of Hot Metal

In the United States, external treatment of hot metal, or pretreatment prior to steelmaking, is done most often for desulfurization. Performed in transfer cars or ladles, this treatment controls sulfur input and reduces slag requirements in steelmaking, allows the use of higher-sulfur raw materials in the blast furnace, and produces low-silicon hot metal (Stubbles 1984; Szekely, Carlsson, and Helle 1989). Magnesium, lime, and fluorspar are common reagents used for this. Limestone, calcium carbide, coke, sodium carbonate, salt-coated magnesium, and aluminum also are used sometimes; consumption is on the order of 4 to 7 kg/t except for salt-coated magnesium, which is added at 0.5 kg/t (Szekely, Carlsson, and Helle 1989; Cameron 1992). The thermodynamics of the process along with case studies are described by D'Orazio (1984), Dukelow (1984), and Pehlke (1984).

Simultaneous desphosphorization and desulfurization is accomplished with soda ash (sodium carbonate) or lime if the metal is low in silicon (Szekely, Carlsson, and Helle 1989). Sodium carbonate (Na_2CO_3) reacts with sulfur, silica, and phosphorus to form

sodium sulfide (Na_2S), sodium silicate ($\text{Na}_2\text{O}\cdot\text{SiO}_2$), and sodium phosphate ($3\text{Na}_2\text{O}\cdot\text{P}_2\text{O}_5$) in the slag. An advantage of this process is that sodium carbonate can be recovered and recycled; however, high refractory wear is typical (Yamamoto, Kajioka, and Nakamura 1980).

Oxygen Steelmaking

In blast furnace steelmaking, steel is produced from hot metal by oxidizing sulfur, phosphorus, carbon, silicon, and other impurities so that they will enter the slag or gas phases, thus separating from the metal phase. The basic oxygen process (BOP) oxidizes impurities in a BOF when the hot metal comes in contact with oxygen. Oxidized impurities rise to the top of the hot metal and are absorbed in a slag, which is formed from lime and dolomitic lime with the addition of other compounds such as fluorspar to improve fluidity. Fluorspar (calcium fluoride) is added in amounts of 2 to 10 kg/t (Peters 1982), either as lump or gravel-sized material, or as briquettes made with about 15% fluorspar fines combined with slag residues from the BOF. The amount of added flux usually is proportioned to the target silicon content by the V-ratio. The V-ratio typically is 2.5 to 4.0 (Peters 1982). The reader is referred to Boynton (1980) and Oates (1998) for the use of lime in steelmaking.

The amount of flux added depends on the silicon, sulfur, and phosphorus content of the metals, and the purity of the flux (Lankford et al. 1985). Typically, 40 to 100 kg of lime per ton of hot metal and 10 to 30 kg of dolomitic lime per ton of hot metal are added to the BOF (Peters 1982; Lankford et al. 1985). By decreasing the silicon content of the hot metal and by lowering the manganese content, the amount of lime required in steelmaking has steadily declined. Increased use of scrap, along with external desulfurization, resulted in lower flux consumption in steelmaking. Typical steelmaking slag now contains the following: 10% to 20% SiO_2 ; 40% to 50% CaO ; 10% MgO ; 15% to 20% iron (mixed oxides); 2% to 5% Al_2O_3 ; and 10% manganese oxide (MnO) and other oxides. Iron oxide content depends on carbon levels attained in the metal; it generally increases with lower carbon levels.

A second function of flux in steelmaking is to provide slag that is neutral with respect to the lining of the steelmaking vessel. The refractory lining in basic steelmaking typically is magnesia brick. To help prevent erosion and dissolution of magnesia brick, 5% to 12% magnesia is maintained in steelmaking slag (Boynton 1980; Peters 1982; Lankford et al. 1985). This also aids in controlling the slag viscosity. Solubility of magnesia is greater in acid slags as the V-ratio decreases. The effect of magnesia on phosphorus removal is questionable.

Electric-Arc Furnace Steelmaking

EAFs are used to make steel and ferroalloys from direct reduced iron, scrap, other ferroalloys, and alloying elements. Oxidation is accomplished by the injection or addition of iron oxide either as mill scale or iron ore. Carbon is added as coke, used carbon electrodes, or coal; and lime is added as flux. In the EAF, both oxidation and reduction processes are used to achieve the necessary purification of the metal and a high retention of alloying elements. In alloy steels, many components are oxidized readily and will report to the slag in an oxidizing environment, but they can be recovered in a subsequent reducing environment. Modern practice for carbon steels is primarily single stage followed by ladle metallurgy. In the past, double-slag, and so-called slag-and-a-half practices followed by ladle metallurgy were used (Reebel 1950; Sharp 1967; Peters 1982; Lankford et al. 1985). In single-slag practice, after the meltdown, oxidizing slag is held in the furnace, and steel is removed and further treated in a ladle. In double-slag practice, slag

and metal are held in the furnace while slag composition is adjusted. In either practice, alloy additions are made prior to the second stage. In slag-and-a-half practice, the first slag is removed, and a lime-fluorspar slag is added to the electric furnace (Lankford et al. 1985).

For oxidizing slags, limestone can be added, but calcined lime and dolomitic lime are used most often for slag formation. Using calcined materials reduces energy consumption compared to using uncalcined fluxes. To protect refractories and to improve power efficiency, limestone and coke are added in some practices to help create a foaming slag. Lime and dolomitic lime also are added to protect furnace refractories. Lime addition ranges from 15 to 50 kg/t (Boynton 1980). Other slag-forming ingredients are fluorspar, silica sand, crushed coke, and aluminum. During melting, oxidation of carbon to gas (CO_2) occurs, and the oxidation of phosphorus, silicon, manganese, and chromium allows their removal to the slag. The V-ratio is maintained over 2.5 in the meltdown state; a range of 2 to 4 is typical (Lankford et al. 1985). Basicity depends on the amount of silica in the charge and in the added flux. Iron oxide content in the slag is inversely related to the carbon content in the bath, as in oxygen steelmaking. An oxidizing meltdown slag might contain 40% to 50% CaO ; 12% to 20% SiO_2 ; 5% to 35% iron oxide (FeO); 3% to 10% Al_2O_3 ; 2% to 12% MgO ; and 5% to 15% MnO (Peters 1982; Lankford et al. 1985). Generally, 40% to 50% CaO is required for effective sulfur removal (Lankford et al. 1985).

Although not used often, the second stage in a two-stage furnace practice is accomplished in a mildly reducing slag in a ladle. There, a basic, nonoxidizing $\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot\text{SiO}_2$ slag is built up from additions of lime, dicalcium aluminate, and aluminum. During the second process stage, metal oxides in the slag are reduced and sulfur enters the slag as calcium sulfide (particularly in low iron-oxide slags). In the double-slag electric-furnace practice, a finishing or deoxidizing slag is formed by reacting coke with lime to form a calcium-carbide slag. High-purity coke and lime are desirable. Fluorspar equal to about 10% of the lime sometimes is added to increase reaction with lime and increase fluidity (Sharp 1967). Silica is added sometimes, and alumina can be added in place of fluorspar. The slag quantity is generally about 2% to 3% of the metal. Typical reducing slag might contain 55% to 70% CaO ; 15% to 25% SiO_2 ; 1% to 3% Al_2O_3 ; 3% to 12% MgO ; and 0.5% to 2% FeO and MnO (Peters 1982).

Ladle Metallurgy

Reagents are added to liquid steel in the transfer ladle for additional refining to remove sulfur, reduce metallic oxides, and condition the slag prior to casting. Additions also are made for alloying and for shape control of inclusions in the cast product. Reagents similar to those for hot metal desulfurization are used. The reagents are added at the top of the ladle or injected. Metallic elements can be added in the form of wire. Typical reagents are magnesium, lime, alumina, aluminum, fluorspar, calcium carbide, calcium-silicon alloy, and prefused dicalcium aluminate (calcium-aluminate). Magnesium is often added in combination with lime. Typical addition rates are 1 to 5 kg/t (Szekely, Carlsson, and Helle 1989). Calcium-aluminate increases deoxidation of steel and has a high capacity for sulfides (Turkdogan 1985). An exothermic synthetic calcium-aluminate mixture comprising 58% dry lime, 30% hematite, and 12% aluminum powder might be added at tap (Gilbert, Monos, and Turkdogan 1988).

Continuous Casting

Fluxes used during the continuous casting of steel and during bottom pouring of ingots often are referred to as *mold powders*. These

are either mix tures of co mpounds or fused synth etic slags formulated to do the following:

- Provide thermal insulation and prevent solidification in the mold
- Prevent oxidation
- Absorb oxide inclusions
- Lubricate at high temperature
- Maintain uniform heat transfer

Mold powders are important for the following physical properties: flowability, melting rate, viscosity, crystallization temperature, inclusion absorption capacity, and insulation characteristics. Mold powder selection is critical because the powders can interact with the metal (Bommaraju 1991).

Mold fluxes are largely silica-based with additions of lime, alumina, fluorspar, alkali metal oxides, and carbon, and are used both as raw mixtures (synthetic flux) and in premelted and sintered forms. More recently, mold powders are fused and spheroidized to form a well-behaved flowable powder to facilitate automatic feeding and uniform melting in the casting mold. Particle sizes range from granules finer than 10 mesh (1.5 mm) down to powders with 90% finer than 200 mesh (0.074 mm). Typical mold fluxes contain 17% to 56% SiO_2 ; 2% to 45% CaO ; up to 25% Al_2O_3 ; up to 15% fluorine (F_2); up to 10% iron Fe_2O_3 ; up to 20% borate (B_2O_3); up to 25% alkali metal oxides (Na_2O , K_2O , lithia [Li_2O]); and up to 30% carbon (C). Amounts vary widely in order to obtain the desired effect. Basicity (CaO/SiO_2) typically ranges from 0.65 to 1.67. Consumption of mold fluxes is 0.3 to 0.8 kg/t in continuous casting, and 1 to 3 kg/t in ingot casting (Branion 1987; McCauley and Koul 1987).

Nonferrous Metallurgy

The use of fluxes in nonferrous smelting is described in depth in Rosenqvist (1974), Moore (1981), Turkdogan (1983), and Habashi (1986). Nonferrous slags are based largely on the formation of iron silicate rather than calcium–aluminum silicate as in ironmaking and steelmaking. Typical nonferrous slag contains 30% to 55% FeO , 30% to 45% SiO_2 , and less than 10% CaO , although variations occur depending on the system. Rosenqvist (1974) and Coudurier, Hopkins, and Wilkomirsky (1985) present phase diagrams of typical nonferrous systems that show the compositional ranges of slags. In copper smelting, silica is the predominant flux, but lime also is added to modify slag viscosity and density.

Limestone is used in small amounts to aid in refining metallic copper, lead, zinc, tin, and antimony (Boynton 1980). Although limestone flux purity and particle size are similar to that used in ironmaking and steelmaking, high-calcium limestone is used most often. Both high-grade siliceous materials and lower-grade siliceous ores are used as fluxes along with limestone. An overview of the technology applied to smelting and refining copper, lead, nickel, and other nonferrous metals was published by Peacey (1989).

Copper

Copper occurs as oxide and sulfide minerals, and recovery of copper from sulfide ores is by smelting. Many copper–sulfide ores contain iron that must be fluxed, and typically silica is used to flux iron and form an iron–silicate slag (fayalite). During smelting, sulfur combines with copper and some iron to form a copper–iron sulfide matte, which is separated from the slag. The matte is converted to metallic copper by oxidation, consequently removing iron and sulfur; copper is further refined to remove impurities (Moore 1981; Turkdogan 1983).

Although copper smelting is done in bath processes and flash-smelting furnaces with oxygen enrichment, flash smelting is the predominant method practiced today (Peacey 1989). The older, reverberatory–furnace practice is described in Anderson (1961), Fowler (1961), and Nicholson, Lockridge, and Beals (1961). Electric-furnace smelting of copper sulfides is reported in detail along with other smelting processes by Barth (1961), Floyd, Grave, and Lightfoot (1980), and Phelps (1991). Slags in reverberatory–furnace smelting, flash smelting, and other processes are similar; however, the Mitsubishi continuous-smelting and refining process differs in that a calcium–ferrite slag is used in the converting furnace.

Copper-bearing concentrates often contain 5% to 10% silica. About 5% silica is added as either pure silica or ore; if additional silica is necessary, it is obtained from recycled converter slag that was used to make copper metal from the matte. Lime is added to break up silicates, take up excess silica from aluminosilicates, and reduce the viscosity of the silica-rich slag. Typically, 3% to 10% limestone or lime-bearing mix is added. A typical smelting slag contains about 30% to 45% FeO ; 30% to 40% SiO_2 ; 5% to 10% Al_2O_3 ; 2% to 6% CaO ; and 2% to 4% MgO (Watanabe, Okada, and Muto 1980). The ratio of slag to metal varies, but it is in the range of 0.6:1 to 1.5:1.

One problem in the recovery of copper is the tendency to form magnetite in the converters, although a certain amount of magnetite is required for high-copper recoveries. Magnetite melts at a temperature higher than either smelting or converting temperatures; has a low solubility in slags and matte; and does not form a silicate because much of the silica present is tied up in other forms. Some free silica is added to combine with magnetite as iron silicate, but the excess silica will react with basic furnace brick. The silica is often of very high purity—greater than 90% SiO_2 (Fowler 1961; Floyd, Grave, and Lightfoot 1980; Watanabe, Okada, and Muto 1980). Siliceous slags are normally used; however, Turkdogan (1983) and Chaubal et al. (1989) have reported that lime-based slags have a lower viscosity; have a higher solubility for magnetite; separate more easily from the matte; and remove arsenic, antimony, and bismuth more efficiently than siliceous slag.

In converters, flux particle size is in the 6 × 25 mm range. Although coarser flux is difficult to inject and to dissolve, finer flux tends to float on the bath and is also a source of dust (Anderson 1961). In the Siros melt process, limestone flux was 5 to 10 mm in size (Floyd, Grave, and Lightfoot 1980).

Lead

Lead is processed by a number of older techniques including sintering followed by smelting in the lead blast furnace, electric furnace, or Imperial Smelting Process (ISP). Several newer direct- and flash-smelting methods such as Kivcet, Outokumpu, and QSL are being utilized also (Castle et al. 1989; Pickard and Crawford 1989). In the blast furnace and ISP processes, lead–sulfide ores are roasted to form lead–oxide sinter, which is charged with limestone and coke to the lead blast furnace or the Imperial Smelting Furnace (Moore 1981). In the latter, lead is collected in the furnace bottom where it separates from slag, while zinc vapor exiting the top is condensed. In the direct- and flash-processing methods, lead is partially or totally oxidized into the slag, then the slag is treated in an electric furnace with carbon (coal or coke) to reduce oxidized lead into lead bullion (Turkdogan 1983). Copper is removed from lead by adding sulfur and by several other processes. Further refining is accomplished by oxidizing impurities with air, lead oxide, sodium hydroxide, or sodium–nitrate flux, and by electro-refining (Moore 1981; Peacey 1989).

These slags are complex. The following is a typical lead blast furnace slag composition (Grant 1980):

- 2% to 12% zinc oxide (ZnO)
- 20% to 25% FeO
- 1% to 2% ferrous iron (Fe_3O_4)
- Up to 2% litharge (PbO)
- 16% to 19% CaO
- 26% to 31% SiO_2
- 5% MnO
- 10% Al_2O_3
- 1% to 2% CaS
- 5% to 10% MgO

Nickel

Nickel ores occur as both sulfides and oxides. Sulfide ores often contain copper-iron sulfides in association with nickel-iron sulfides. Processing of sulfide ores is accomplished in reverberatory or flash-smelting furnaces and horizontal converters (Moore 1981; Pickard and Crawford 1989); flash converting also is used (Phelps 1991). Copper and nickel sulfides are separated from the matte by crystallization, grinding, and froth flotation; then copper and nickel sulfides are refined further. In some nickel ore smelting, slag formation is complex because of the presence of MgO in various silicate minerals. The slag is typically iron- and silica-rich, but with elevated MgO levels. MgO increases the melting point, allowing olivine, $(\text{Mg,Fe})_2\text{SiO}_4$, to crystallize out of the melt. This can be countered with silica and lime addition; lime decreases the viscosity of the melt (Davey, Segnit, and Boow 1980).

In New Caledonia, in the South Pacific, an oxide ore comprising a nickel-bearing hydrated silicate of iron and MgO contains 37% SiO_2 ; 2.2% Al_2O_3 ; 23% MgO; 20% Fe_2O_3 ; 2% Cr_2O_3 ; 0.3% CaO; and 2.2% nickel (Ni). It was sintered with gypsum and smelted in a blast furnace to an iron-nickel matte. This was treated further in a converter to remove iron (Thurneysen, Szczeniowski, and Michel 1961; Habashi 1986). At the now-closed smelter at Riddle, Oregon, garnierite, a magnesium silicate containing alumina, was smelted. The ore contained 25% to 38% MgO; 45% to 55% SiO_2 ; 1% to 3% Al_2O_3 ; 1% to 2% CaO; 8% to 15% Fe; and 1.5% Ni. In the Uginé process, silicon as ferrosilicon (FeSi) was used as the reductant, and the silica that formed was removed in the slag. Phosphorus was removed by oxidizing the bath with iron ore in the presence of a lime-rich slag. The metal was further refined with slag containing lime and fluorspar (Coleman and Vedensky 1961).

Tin

High-grade tin-oxide concentrate is smelted in reverberatory and electric furnaces, and low-grade concentrate is smelted in blast furnaces, kilns, and horizontal furnaces (Castle et al. 1989). In the first stage of a two-stage process, part of the oxide is reduced to metal with the formation of a ferrous-silicate slag containing a small amount of lime and unreduced tin as a tin silicate. First-stage slags typically contain 30% to 40% SiO_2 ; 15% to 25% FeO; 5% to 15% CaO; and 5% to 25% SnO_2 . In the second stage, tin silicate is reduced by iron metal to form iron silicate and an impure tin, which is recycled. Second-stage slags from Southeast Asia typically contain 24% to 28% SiO_2 ; 9% to 11% Al_2O_3 ; 20% to 22% CaO; 12% to 20% FeO; 2% to 6% MgO; and impurity metals (Habashi 1986).

ECONOMIC FACTORS

Because the iron and steel industry is a large consumer of flux, consumption of limestone and dolomite is influenced strongly by steel-

making. The USGS reports that the United States enjoyed a long economic expansion that lasted from 1991 until March of 2001, followed by a short recession of about eight months. Shipments of steel products grew for six consecutive years until 1998, increased slightly in 1999 and 2000, and then dropped during the recession of 2001. Steel consumption actually peaked at 120 Mt in 2000 and decreased to 107 t in 2002, the lowest consumption since 1995. Growth in U.S. economic output in 2002 was projected as 2.4% or less (Fenton 2002).

In the steel industry, low-priced imports continue to affect domestic steel production—amounting to 30% of U.S. consumption. During the period from 1998 to 2002, 35 steel companies filed for bankruptcy protection (Miller 2002b). The crisis in the steel industry continued in 2003 and was reflected in the fluxstone industry as well. In 2004, rising consumption in China and an upturn in the economy caused a significant increase in steel production.

The market for limestone and dolomite greatly influences the pricing of fluxstone because it is part of the much larger crushed stone industry; however, fluxstone purity is an important consideration that limits the selection of sources. According to the USGS, 71% of crushed stone was limestone and dolomite, but only 14% was for the chemical and metallurgical industries. About 20% of limestone and 7% of dolomite was used in the chemical and metallurgical industries. Because less than 5% of this is used as flux in the chemical and metallurgical industries, overall flux usage is less than 1% of the crushed stone industry. Consequently, fluxstone use is not followed closely as a separate commodity (Tepordei 2002a).

In 2002, imports of foreign pellets amounted to 17.4% of U.S. blast furnace consumption. Major sources of pellets were approximately one-half from Brazil and one-half from Canada (Kirk 2002). Greater importation of pellets into the United States from Brazil is limited at present only by the cost of transportation to inland steel mills. The proportion of fluxed pellets, if any, was not indicated.

Because limestone, dolomite, and silicate fluxes are plentiful, foreign trade is limited to the boundary regions between countries. Imports and exports are inconsequential in the overall usage patterns at present; however, fluorspar, which is used at a rate of up to 10 kg/t of steel, is almost entirely imported because of high domestic production and transportation costs (USBM 1991). Metallurgical fluorspar imports and domestic consumption were about 51,000 t in 1998, with 70% from China; 20% from South Africa; and 10% from Mexico; almost the reverse situation of 15 years ago when Mexico was the largest source (Hodge 1998; Miller 2002a). In 2002, the U.S. government placed various quantities up for sale from the National Defense Stockpile, but there were no buyers, a situation that continued into 2003. Demand for metallurgical-grade fluorspar is continually decreasing in steel and allied industries.

Because metal consumption per capita in industrialized nations is 30 times that of underdeveloped nations (USBM 1991), worldwide potential for increased metal production and complementary consumption of flux is very large. Future shortages in mineral commodities were not predicted 10 to 15 years ago. In a review of the state of the metals industry (Davis 1989), it was suggested that consumption of ferrous and nonferrous metals would cease growing around 1960. In fact, consumption trends turned negative in the late 1980s (Davis 1989), attributed to decreasing economic growth in industrialized countries and the lessening intensity of metal use in the service and manufacturing industries. Several economists also proposed that the demand for raw materials had become dissociated from economic growth (Davis 1989). This was particularly true in Japan and the United States, where the impact was greatest on the steel industry, the largest user of flux minerals.

The implication of this negative trend was that economic recovery would not necessarily result in increased demand for metals (and hence fluxes). To stimulate further growth, the suggestion was made that new demand needed to be created, driven by market development. This changed, however, with the modernization of China and the creation of a market-driven economy there. In 2003 China's economic growth became evident, and in 2004 it was so strong that shortages in all types of raw materials were apparent, driving up prices significantly worldwide (Fortner 2004). India also is on the verge of new economic growth. Although this rate of economic growth is not evident in the United States, raw materials prices still are affected. Fluxstone is not a likely participant in this growth because of the universal availability of many of the resources. China currently is trying to dampen its growth rate to more manageable levels.

Changes in South Africa and the Commonwealth of Independent States (CIS; formerly the U.S.S.R.) during the last decade and increased trade with China have altered the supply-and-demand situation of certain minerals and steel, which potentially can affect flux consumption. Greater imports of metals from these countries by the United States will impact domestic flux production and consumption. Even with increased imports of metals and other mineral commodities, it is unlikely that any large-scale trade in fluxstone or silica flux will occur because of their relative abundance, low unit values, and high transportation costs.

Other factors that could affect the flux industry are the introduction of the North American Free Trade Agreement (NAFTA); wider use of the Internet; closure of the U.S. Bureau of Mines (USBM) and assumption of some of its activities by the USGS; continued development of alternate ironmaking technologies; and foreign ownership of U.S. iron mines and steel companies.

GOVERNMENT, ENVIRONMENT, AND HEALTH CONSIDERATIONS

Government influences mineral and metal markets through labor laws, land use and environmental regulations, trade and energy policies, and funded programs and research. In the United States, the flux industry can be affected by actions of the Department of the Interior, the Department of Energy (DOE), the Environmental Protection Agency (EPA), the Occupational Safety and Health Administration (OSHA), the Mine Safety and Health Administration (MSHA), and the Bureau of Land Management (BLM), to name a few.

Mining and quarrying have effects on the environment, particularly land use. In some instances, the crushed stone industry has developed near populated areas, causing problems with dust, noise, blasting, trucking, and so forth with its closest neighbors. Although little emphasis was placed on the environment in years past, that has changed because of increased public awareness and as the result of state and federal regulations. Environmental regulations that affect mining and quarrying include reclamation of process water and solid waste, reduction of dust and noise, and control of air and ground shock from blasting.

For updates on minerals, land-use planning, and mining law, readers should contact the BLM (<http://www.blm.gov/nhp/index.htm>). For information on mineral statistics, minerals and the environment, recycling, or mining, readers should contact the USGS (<http://www.usgs.gov>).

In 2002, tariffs on steel imports became important. To temporarily slow steel imports by increasing prices, the U.S. government introduced three years of tariffs up to 30% on some imports, under Section 201 of the 1974 Trade Act. During this time the domestic steel industry began consolidating in an attempt to become more efficient and competitive. Foreign governments objected, and the

U.S. Department of Commerce exempted 727 special types of imported steel products. It also became apparent that support for the steel industry was waning, and foreign trade cases were settled in favor of importers. In 2003 the tariffs essentially were abandoned.

Environmental regulations continue to affect the steel industry. For industrial facilities built between 1962 and 1977, EPA is developing regulations that will require limitations on SO₂, NO_x, and particulate matter emissions. Lime plants, in particular, will be affected by these emissions requirements; some have been forced to close already. The lime industry has been identified as a source of a wide range of hazardous air pollutants (Miller 2002b). Some foreign steel mills have been exposed to radioactive materials from stolen radioactive sources, and there is additional potential exposure from scrap hospital equipment. Mercury is another element that has received increased attention lately. Potential point sources are lime kilns burning coal or oil, and copper smelters, among others (Fenton 2002).

Recycling is a good source of scrap in both the iron and aluminum industries; however, consumer recycling has reached equilibrium. Because of impurities such as copper in iron, many sources of scrap are limited in use. As a result, environmental and some industry groups suggest that products be designed for recycling.

In January 2002, the U.S. government passed the Small Business Liability Relief and Brownfields Revitalization Act, which incorporated both the Brownfields Revitalization and Environmental Restoration Act and the Small Business Liability Protection Act. (Brownfield sites are abandoned industrial sites requiring environmental cleanup prior to reuse.) This act authorized funding for assessment programs and subsequent cleanup, and made specific property owners exempt from liability under Superfund laws (Fenton 2002).

FUTURE TRENDS AND OPPORTUNITIES

In the United States, the consumption of fluxes largely depends on the state of the steel industry, which historically is cyclical. During the period from 2002 to 2004, the steel industry has recovered from a depressed market (1999 to 2002) into a growth industry fueled by an economy that supports higher steel prices even as the costs of raw materials increase. On a worldwide basis, growth in China and other developing countries is driving raw materials prices higher, particularly affecting coke and iron oxide pellets. Significant merging has occurred in the industry during these times. Consolidation of U.S. steel mills is nearly complete unless additional mergers of steel companies occur. Although the steel industry enjoyed high prices and strong demand resulting from moderate growth in the economy in 2004, future downturns can be expected.

Increasing fuel costs and demands for environmental compliance will help to increase steelmaking costs, making it more difficult for domestic steel to compete. Both metal production and flux consumption will be influenced by new process technologies, recycling, and substitution (Castle et al. 1989). Trends that will increase competition for steel include the use of composite and lightweight materials in transportation vehicles; more use of high-technology devices; and miniaturization. Substitution by plastics, composites, and lightweight alloys, including aluminum, will impact the use of steel and attendant flux consumption; however, increased use of aluminum will require more fluorspar consumption. Space requirements for slag disposal and the need to contain effluent from slag dumps (to prevent undesirable elements from entering the environment) led to the development of metallurgical processes that demanded less flux for slag production.

The current blast furnace practice of using domestic iron ore pellets with a silica content of only 5% requires a blast furnace slag practice that dictates the amount of flux consumption; therefore,

further reductions in flux consumed per ton of hot metal are unlikely. The continuing trend is to use fluxed pellets in blast furnaces, although the amount of flux used in pellets from different suppliers varies widely (1% to 11%). In 1990 fluxed pellets comprised 34% of domestic pellet production (Ranade 1992). In 1993 the proportion of fluxed pellets increased to 42%, and by 2002 it had reached 66% (Kirk 2002). Recycled steelmaking slag that contains lime presently provides the additional flux needed by many furnaces. Sinter plants are useful for recycling steel-plant wastes, but environmental pressures, particularly for smokestack emissions, may prevent such recycling. The potential of converting sinter plants to lime calcination plants is being investigated.

In steelmaking, new slag functions might redefine flux requirements. These include foaming to provide a blanket over the bath to achieve post-combustion of gases, allowing adequate heat transfer, or slag splashing, to protect vessel linings. For example, at times both limestone and lime could be used in the same smelting vessel. A decrease in the consumption of fluorspar in BOF steelmaking also is likely to continue. The practice of continuous casting, which affects consumption of mold powders, is now the dominant mode of casting steel (Fenton 2002).

High fuel prices, particularly for natural gas and coke, have renewed interest in direct ironmaking and direct steelmaking processes that can use coal. Direct ironmaking very likely will require a different slag practice than blast furnace ironmaking, so flux requirements could change. Direct ironmaking processes will use coal in preference to coke, which will increase the sulfur burden. Use of lower-grade coals also could require the alteration of flux practices because of higher ash contents.

In one direct ironmaking process, iron ore concentrate is mixed with flux and coal, pelletized at low temperature, and then reduced and melted on a rotary hearth furnace. The slag and metal separate from each other during melting. Subsequent cooling and magnetic separation result in a pig iron "nugget" that can be charged to electric furnaces. The process results in the production of pig iron nodules, which are desirable as electric furnace feed. One such process has operated successfully at pilot scale. Commercial scale could be reached within the next several years (Huskonen 2001; Negami 2001). Proprietary slag modifiers and fluidity enhancers are added to enhance slag-metal separation.

The rise of mini-mills, the desire by steel producers to decrease coke consumption in order to meet environmental regulations, and increased recycling of scrap are resulting in greater use of EAFs. Although mini-mills accounted for only 6% of U.S. steel production in 1992 (Ashby 1992), in 2002 mini-mill and specialty mill production of steel increased by 8% over 2001 levels, and total EAF production exceeded 50% of total steelmaking capacity (Fenton 2002). Consequently, production from the established BOF route was less than 50% of total steel production in 2002. One mini-mill producer became the third largest domestic steel producer and would have been ranked higher except for mergers of other steel companies. If major steel producers adopt mini-mill and EAF practices, the demand for lower-silica iron sources is likely to increase, and a further decrease in flux consumption is likely as well.

Fluxes Used in Fusion Welding and Brazing

R. David Thomas Jr. and Dan Kay

INTRODUCTION

Brazing and welding are processes for bonding two metal surfaces. Both methods may use a fluxing material to prevent the oxidation of the surfaces to be joined and to facilitate melting of the bonding metal or the metallic surfaces that are being joined. Brazing involves the use of a brazing filler metal (BFM), which is melted to form the union. The brazing process is carried out at temperatures higher than 450°C (840°F) but lower than the melting temperature of the metal to be joined, whereas welding involves the melting of the actual metal surfaces to be joined. A third process, soldering, discussed in the 6th edition of *Industrial Minerals and Rocks*, is not included here because fluxes used in soldering are generally organic and not mineral based.

FUSION WELDING

Fusion welding processes use heat to melt two surfaces, usually the edges of the same material, joining them together to form one complete surface. A clean surface and intimate contact are required to assure a successful weld. Ideally, intimate contact is achieved when the atomic spacing at the interface of the welded surfaces is equal to that of the parent material (*Van Nostrand's Encyclopedia of Science* 1968). Gas welding, in which heat is supplied by a flame, and electric arc welding are the most common types of fusion welding. In arc welding, an arc struck between the welding electrode and the base metal melts both the electrode and the base metal to form the weld.

Arc welding processes fall into several categories:

- *Shielded metal arc*, utilizing an electrode with a flux covering and a metallic core, commonly 3.2 to 6.4 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) in diameter and 225 to 450 mm (9 to 18 in.) in length, often called “stick electrode”
- *Submerged arc*, in which the electrode is a metallic wire of similar diameter fed from coils or drums and the arc is completely submerged by a granular flux
- *Flux cored arc*, a tubular continuous wire formed from a strip which surrounds the fluxing ingredients and is subsequently drawn to diameters ranging from 1.2 to 2.4 mm (0.045 to $\frac{3}{32}$ in.)
- *Electroslag*, in which the wires are continuously fed into a molten, electrically conductive slag that covers the weld pool and fuses the sides of the adjacent thick, vertically oriented, metal plates

Each of these four welding processes depends on the use of fluxes and is described in greater detail in the next section. Several other fusion welding processes are in use, all of which depend on a heat source sufficient to melt the materials to be welded. Commonly used heat sources are an oxy-acetylene (or other fuel) flame or an electric current in which the heat is generated by the resistance to the flow of current, as in spot or seam welding. These and two other arc welding processes, gas metal arc and gas tungsten arc, are not included in this chapter because they do not make use of fluxes.

Function of Fluxes

As the term is used in the welding industry, fluxes are materials used to promote the joining of metals by fusion welding. As used in this chapter, the term applies to mineral formulations used in welding procedures in which their primary and/or secondary function (Lawrence 1983; Griffiths 1985) may be the following:

- Shielding gas formers—volatile compounds and mineral substances that, when heated, give off gases that shield the arc and weld pool from the atmosphere
- Slag formers—minerals that protect the weld metals as they both solidify by forming a molten slag when operating temperatures are reached
- Slag modifiers—minerals that control the physical properties of the slag (melting point, freezing range, conductivity, wettability, fluidity)
- Arc stabilizers—mineral compounds that, with heat, evolve elements with low ionization potential that stabilize the arc
- Deposition rate augmenters—metallic additions that increase the rate of deposition of the weld metal
- Deoxidizers—metallic additions, including iron powder and ferroalloys, that are added to remove free or combined oxygen from the molten metal in the weld pool
- Alloying agents—metallic substances added to flux formulations to enhance the properties of the weld metal
- Fluxing agents—minerals that are active in the removal of impurities from the weld

In addition, flux formulations may contain materials that serve as binders and extrusion aids in the manufacture of coated welding rods or promote agglomeration and extrusion processes in the manufacture of granular flux.

Table 1. Minerals and other materials used in arc welding fluxes

Arc Stabilizers	
Titania—Purified white mineral	
Potassium oxalate—Infrequently used	
Lithium carbonate—Infrequently used	
Gas-Forming Materials	
Cellulose—Purified wood pulp	
Wood flour—Raw wood pulp	
Limestone—Produces CO and CO ₂	
Fluxing Agents	
Cryolite—Strong fluxing agent	
Barium fluoride	
Lithium fluoride—Very effective flux	
Lithium chloride—Infrequently used	
Witherite (BaCO ₃)—Produces CO and CO ₂ as well as fluxing agent	
Fluorspar—Strong fluxing agent	
Slag-Forming Materials	
Bauxite (Al ₂ O ₃)—Raises melting temperature & viscosity	
Feldspar	
Fluorspar—Decreases viscosity of slag	
Ilmenite—Impure form of rutile (TiO ₂)	
Rutile—Unrefined TiO ₂	
Cristobalite (SiO ₂)—For strong acid slag	
Wollastonite (CaSiO ₃), Dolomite (CaMg(CO ₃) ₂)—Neutral slag formers	
Zirconia—Helps slag removal	
Magnetite (Fe ₃ O ₄)—Magnetic iron oxide	
Periclase (MgO)—Raises melting and viscosity	
Pyrolusite (MnO ₂)	
Slipping Agents	
Bentonite clay, Kaolin clay, Mica, Talc, Glycerin—Used in mineral-coated arc welding electrode manufacture to facilitate extrusion	
Binding Agents	
Sodium silicate, Potassium silicate—For extruded arc welding electrodes (potassium allows AC arc welding)	
Dextrin, Gum arabic, Sugar—Used occasionally for special situations	
Alloying and Deoxidizing Ingredients	
Ferrosilicon—Removes oxygen and oxides from weld and may add Si to weld	
Ferroaluminum—Strong deoxidizer	
Ferrotitanium—Deoxidizer and grain refiner in weld	
Ferro-aluminum-titanium—Combined deoxidizer sometimes used	
Zirconium alloy—Deoxidizer and sometimes improves slag removal	
Ferromanganese—Modest deoxidizer often used with ferrosilicon	
Electrolytic manganese—Commonly used to add Mn to weld metal	
Nickel powder, Chromium metal powder, Ferrovanadium, Ferrotungsten or tungsten powder, Other alloying ingredients—Alloying of steels and nonferrous weld metals and for surfacing weld overlays for hardness or corrosion-resisting properties	

Adapted from Linnert 1994.

Fluxes and flux formulations used in pyrometallurgical processes (and the slags produced from them) are generally referred to as acid, basic, or neutral. As with smelting fluxes (Kokal and Renade 1993; see also the Fluxes for Metallurgy chapter in this volume), acid fluxes (e.g., silica) generally form acids in water; basic fluxes (calcium carbonate and lime) form bases in water; and

Figure 1. Schematic illustration of the shielded arc welding process

fluorspar, or calcium fluoride, is a neutral substance because it is the reaction product of a base and an acid.

Minerals commonly used in welding fluxes are listed in Table 1.

Coverings of Shielded Metal Arc Electrodes

Covered electrodes are the most widely used fusion welding materials for joining metals (AWS 1991a). Because they are supplied in individual rods from 225 to 450 mm (9 to 18 in.) long, they are often referred to as “stick” welding rods. Shielded metal arc welding is often preferred for use in small welding shops because light-duty welding power sources, either transformers or rectifiers, are readily available and can be connected into 110- or 220-volt electrical outlets. Rural operators have portable, gasoline-powered generators to provide welding services where power may not be available. Improved electrode formulations and power sources allow operators to acquire the needed skills for sound welds in local training schools in a relatively short period of time. Although many newer processes have been developed over the years, the simplicity of the shielded metal arc welding process provides the primary means for small welding operations and for many maintenance functions in even the largest industries.

In the shielded arc process the arc is struck between the base metal and the filler metal exposed at the end of the self-shielded coated electrode. The heat from the arc melts both the electrode and the base metal, forming a weld pool that is protected from atmospheric contamination by a shield formed of the gases that evolve from the constituents of the electrode coating. The coating also includes appropriate slag-forming, arc-stabilizing, and alloying agents. The consumable electrode is hand-fed into the weld. The nature of the electrode covering and its function within the arc during the welding operation are illustrated in Figure 1.

The major components of the coating determine the four major types of covered electrodes: cellulosic, rutile, lime or lime-titanium, and iron powder. Some of these include two subclasses: one for use only with direct current and one that may be used with either direct or alternating current. Most arc welding with stick electrodes is done with direct current, so as to provide a steady current. Alternating current power sources are based on transformers that are adapted for welding voltages and are relatively inexpensive; however, it can be difficult to maintain the arc because of the polarity reversals of alternating currents.

Cellulosic covered electrodes, as their name implies, incorporate considerable wood flour or other forms of refined cellulose. The combustion of the cellulose provides the shielding gas that surrounds the arc. Slag-forming materials are incorporated in the

coating to control the molten metal as it flows into the joint. For welding in other than the flat position, for example in pipeline welds where the operator must weld completely around the pipe, a fast-freezing slag is needed to hold the molten weld metal in the joint while the weld is solidifying. This is one of the principal uses of cellulosic electrodes. An operator may start the joint in the six-o'clock position (overhead) and progress upward to the three-o'clock position (vertical), thence to the twelve-o'clock position (flat); periclase is often used for increasing the fusion temperature of the siliceous slag. The deoxidizers are usually a combination of ferromanganese and ferrosilicon that contributes to the slag when the manganese and silicon combine with oxygen in the arc. Titania is present to stabilize the somewhat longer arc, allowing the operator greater flexibility when welding in all positions, either uphill or downhill. Cellulosic electrodes for use with alternating current contain potassium silicate, rather than sodium silicate, as a binder; the potassium ionizes the arc more readily, giving it stability as the current alternates between positive and negative polarity.

Rutile electrode coatings contain more than 50% rutile, providing a very stable arc. For gas shielding the electrode also contains some cellulose, along with deoxidizers, and arc stabilizers. As with the cellulosic electrodes, rutile types can be used in all positions, but the arc does not penetrate as deeply as does the cellulosic type. This allows the weld to bridge gaps more readily, and thus rutile-coated electrodes are preferred when poor fit-up conditions prevail. A dense slag that is easily removed forms uniformly over the weld surface. The se electrodes are preferred by less-skilled operators and consequently are used for a wide variety of maintenance operations. The rutile type made for use with alternating current has a very stable arc, and, with its low penetrating character, is especially suitable for sheet metal joining. Another variation of rutile electrodes contains a relatively large amount of iron powder, which fuses and adds to the weld metal.

Lime type electrodes are generally called basic type electrodes because they produce a basic slag formed largely from limestone and fluorspar. Decomposition of calcium carbonate forms carbon dioxide and carbon monoxide that shield the arc from atmospheric contamination. During manufacture with alkaline liquid silicates as binders, lime type electrodes are baked at much higher temperatures than those containing cellulose and thus produce welds characterized by low hydrogen contents. Such electrodes frequently are referred to as low-hydrogen electrodes, allowing them to be used on low-alloy steels where hydrogen cracking can be a problem. They are suitable for use on direct current with the electrode connected to the positive terminal. Unskilled operators may find it more difficult to maintain a steady arc with these electrodes; thus variations with up to 8% titania (lime-titania electrodes) have been developed to improve arc stability. With the addition of potassium silicate as the binder, this type of basic electrode can be used with alternating current, although the alternating current types are often used with direct current as well. Basic electrodes are usable in all positions, although their slags are somewhat more difficult to remove; the addition of titania and sometimes zirconia makes the slags more friable when cold and thus more readily removed. As with the cellulosic types, iron powder additions have improved the ease of operation and provide additional weld metal, and are now the most popular of the low-hydrogen types. They are used not only for carbon steels, but also for stainless steels, low-alloy steels, and even some nonferrous alloy electrodes.

Electrode coatings with very high amounts of iron powder, in which the thick coatings comprise as much as 50% of the electrode weight, are also available. The iron powder adds considerably to the amount of weld metal produced by the metallic core; thus these

Source: AWS 1991a.

Figure 2. Schematic illustration of the submerged arc welding process

electrodes sometimes are referred to as high-efficiency electrodes. The relatively thick covering and the conductivity provided by the iron powder allow the electrode to rest on the weld sea m to produce a flat groove weld. This sometimes is referred to as gravity welding.

Fluxes for Submerged Arc Welding

In some operations, submerged arc welding (SAW) is a fully automatic method performed with a continuous electrode and a layer of granular flux (Griffiths 1985; Althouse et al. 1997). The flux, composed of silicates, with or without deoxidizers and alloying agents, is fed automatically from a hopper. The arc, struck between bare filler metal wire and the base metal, melts some of the flux to form a protective layer of molten slag over the weld pool. Unmelted flux can be recovered by means of vacuum and recycled (see Figure 2).

SAW is most commonly used in large fabrication operations where the process is fully automatic. A machine supporting the wire and flux feeders is mounted on a device that travels over the weld groove, tended by an individual who positions the machine, starts the arc, and observes and monitors the operation. It may be employed to make a single weld pass in steel plates up to 2.5 cm (1 in.) thick or to make multiple passes for greater thicknesses. All welding is done in the flat or horizontal fillet position. For very thick welds or for fast travel rates, the speed of the operation is greatly augmented by the use of multiple wires fed into the joint, each energized with different electrical polarities. The fluxes selected for the operation are determined by the welding process requirements, including penetration of the weld with the base metal, the contour of the weld deposit, the ease of slag detachment, and the metallurgical properties of the weld metal.

SAW can also be done manually with a combination electrode and wire feed cable attached to an electrode holder with a small hopper for flux built into the holder (Althouse et al. 1997). The operator guides the electrode along the joint.

Submerged arc fluxes protect the depositing weld metal from the atmosphere primarily by the granular flux covering and the vapor and other gases formed during fusion in the arc. The y are supplied in three forms: prefused, bonded, and agglomerated.

Prefused Fluxes. Prefused fluxes are produced by melting the ingredients in a n electric furnace. After melting, the flux is

Table 2. Classification of submerged arc fluxes

Symbol	Chemical Constituents	Composition Limits, %
MS (manganese-silicate)	MnO + SiO ₂	50 minimum (min)
	CaO	15 maximum (max)
CS (calcium-silicate)	CaO + MgO + SiO ₂	55 min
	CaO + MgO	15 min
ZS (zirconium-silicate)	ZrO ₂ + SiO ₂ + MnO	45 min
	ZrO ₂	15 min
RS (rutile-silicate)	TiO ₂ + SiO ₂ 50	min
	TiO ₂	20 min
AR (aluminate-rutile)	Al ₂ O ₃ + TiO ₂ 40	min
AB (aluminate-basic)	Al ₂ O ₃ + CaO + MgO	40 min
	Al ₂ O ₃ 20	min
AS (aluminate-silicate)	CaF ₂	22 max
	Al ₂ O ₃ + SiO ₂ + ZrO ₂	40 min
	CaF ₂ + MgO	20 min
	ZrO ₂	22 max
AF (aluminate-fluoride-basic)	Al ₂ O ₃ + CaF ₂	70 min
FB (fluoride-basic)	CaO + MgO + CaF ₂ + MnO	50 min
	SiO ₂ 20	max
	CaF ₂	15 min

Table 3. Flux characteristics

Symbol	Type	Basicity Index	Application
CS	Bonded	0.5, strongly acid	Tolerates high current. Easy slag removal. High oxygen levels in weld.
CS	Fused	1.1, neutral	Moderately good toughness. Slag removal difficult in multiple-pass groove welds.
MS	Bonded	0.8, mildly acid	Fast weld travel speeds. Does not tolerate rusty steels.
AB	Bonded	1.1, neutral	Used only with DC power. Can tolerate rusty steels with suitable deoxidizers.
FB	Agglomerated	3.5, strongly basic fluoride	Excellent for mechanical properties, especially in multiple-pass welds. Slag removal difficult.

Adapted from Linnert 1994.

quenched and crushed. The resulting product is a glass that has good chemical homogeneity. Prefused fluxes are generally non-hygroscopic. Unfused portions of the flux can be reused without a change in the chemical composition of the flux and are suitable for high welding speeds. The greatest disadvantage of prefused fluxes is that alloy additions and deoxidizers cannot be incorporated into the flux because of the high-temperature prefusing operation.

Bonded Fluxes. Bonded fluxes are produced by binding the constituents together with potassium or sodium silicate, which results in the pelletization of the flux. The advantages over prefused flux are: the deoxidizers and ferroalloys are retained; a lower-density flux allows better protection from thicker flux blankets; and the resulting slag is removed more easily after welding. The disadvantages of bonded flux are that, during vacuuming, the composition may be altered, and they are more hygroscopic, making the welds subject to hydrogen cracking.

Source: AWS 1991a.

Figure 3. Schematic illustration of the two types of flux cored wires

Agglomerated Fluxes. Agglomerated fluxes are similar to bonded fluxes except that a ceramic binding agent is used and, thus, higher processing temperatures are required. Agglomerated fluxes tend to be slightly less hygroscopic than bonded fluxes, but their higher processing temperatures limit the recovery of deoxidizers and alloying ingredients.

Submerged arc fluxes are often classified by their principal ingredients, as shown in Table 2.

The mechanical properties of the welds produced by SAW are influenced greatly by the selection of the flux. Those fluxes that form acid slags (high in silica) generally are not used where stringent requirements for strength, ductility, or toughness are to be achieved. To characterize the nature of the slag-forming characteristics of various fluxes, the basicity index (BI) is determined using the following expression (Tuliani, Boniszewski and Eaton 1969):

$$BI = \frac{CaO + CaF_2 + MgO + K_2O + Na_2O + BaO + SrO + \frac{1}{2}(MnO + FeO)}{SiO_2 + \frac{1}{2}(Al_2O_3 + TiO_2 + ZrO_2)}$$

Fluxes with a BI less than 1.0 are called acid fluxes, those with a BI between 1.0 and 1.5 are neutral, and those with a BI greater than 1.5 are basic. Table 3 shows several types of commercially available fluxes with different characteristics and uses.

Flux Ingredients in Flux Cored Wires

There are two major types of flux cored wires: (1) those requiring an external shielding gas, usually carbon dioxide or a mixture of

Table 4. Typical flux formulations for steel flux cored electrodes

Type of Electrode	AWS Designation			
	EXXT-1, Gas Shielded	EXXT-3, Self Shielded	EXXT-5, Gas Shielded	EXXT-8, Self Shielded
Essential operating characteristics and application	Spray-transfer, direct-current electrode positive (DCEP), suitable for multiple-pass welding, medium slag	Spray-transfer, DCEP, suitable for single-pass welding of thin base metal	Globular transfer, single- and multiple-pass welding, thin slag blanket	All-position deposition, direct current electrode negative (DCEN), good low-temperature toughness
Core Ingredients	Percentage of Ingredients in Core by Weight			
Cryolite	5	5	15	5
Dolomite	15	NS*	NS	NS
Feldspar	7	10	15	5
Ferroaluminum	NS	20	NS	15

* NS = not significant.

carbon dioxide and argon; and (2) those not requiring an external shielding gas, called “self-shielded.” The schematic sketches in Figure 3 illustrate the two classes.

Two groups of mineral ingredients are used in gas-shielded electrodes: rutile and lime-fluoride. The self-shielded types generally utilize relatively large amounts of metallic aluminum powder, the aluminum providing a vapor that protects the metal deposition as well as serving as a deoxidizer. Table 4 shows the composition of the flux ingredients in four of the most common commercial types of flux cored wires.

Flux cored arc welding offers all-position capability in wire diameter under $3/32$ in.; larger sizes are generally used only in the flat or horizontal fillet position. For most welding out-of-position, the wire size most commonly used is 1.2 mm (0.045 in.). Some formulations are not readily produced in diameters that small, especially those that require large amounts of flux (which limits the diameter to that which the tubular material can be reduced). The ingredients largely determine the nature of the arc. Arc stabilizers promote spray type arc transfer and basic ingredients, such as fluorspar, promote a globular type of transfer. As in covered electrodes, flux cored wire can incorporate ferromanganese and other ferroalloys for deoxidation. The process allows core formulations with substantial additions of alloying ingredients for welding low-alloy steels. Stainless steel, nickel-, copper-, and cobalt-based alloy sheathed flux cored wires are produced for joining stainless steel, nonferrous alloys; for weld surfacing; and for a wide variety of other applications.

Fluxes for Electroslag Welding

Electroslag welding (ESW) is used to weld butt joints on thick metal (Griffiths 1985; Althouse et al. 1997). The weld is performed vertically, moving upward. Before the weld is started, a conductive flux material 50 to 75 mm (2 to 3 in.) thick is laid down between the two pieces to be joined. An arc is struck between one or more continuous, consumable electrodes, either solid wire or flux-cored,

and the base metal. When the flux becomes molten, the arc is stopped, but the electricity continues to flow from the electrodes, through the electrically conductive slag, to the base metal. The flux (slag) remains molten because of its resistance to the flow of electricity. The molten flux melts the base metal and the continuously fed filler to form the weld. Movable water-cooled copper shoes, one on each side of the joint, confine the molten flux, filler metal, and weld metal to the gap and are moved up as the weld progresses upward. The electrode can be oscillated automatically when very thick plates are welded. Figure 4 illustrates the ESW process.

The process depends on a molten flux that continuously fuses both sides of the welded joint and the filler wires that project into the flux bath. As with fluxes used in electric furnace refining of alloy steels, the components of the flux must have melting temperatures in a range well below that of the steel and remain fluid with minimal vapor formation at temperatures above those of the steel being welded. At these temperatures the slag must be chemically stable and electrically conductive in order to provide the thermal energy to melt both the edges of the base metal and the filler metal. If the slag becomes too conductive during the operation, an arc will form above the slag pool, thus melting the electrode wires but failing to fuse the side walls of the joint. Most commonly, fluxes are formulated with combinations of lime, alumina, and silica. Fluorspar increases the fluidity and the electrical resistivity of the molten slag; titanium and manganese oxides tend to increase the conductivity. Highly basic flux combinations are thought to give exceptionally low oxide inclusions that, as in the welded state, will have large grain sizes and relatively slow solidification rate. Post-weld heat treatment will improve greatly the weld properties of these coarse-grain welds, both in the weld metal and the heat-affected zones.

For ESW of thick stainless steels, a basic flux with less silica and more lime and fluorspar generally is preferred in order to reduce the loss of chromium in the weld metal. Alumina is needed

Source: AWS 1991a.

Figure 4. Schematic illustration of the electroslag welding process

in such fluxes to provide the desired fusion temperature range and conductivity. One typical flux composition contains 5% lime, 15% fluorspar, 5% magnesia, 20% pyrolusite, 20% alumina, and 35% silica (Linnert 1994).

On the exterior weld surfaces on both sides of the joint, the slag solidifies against the copper shoes as the weld progresses upward. The amount of slag depends on the thickness of the plates being welded and is considerably less in very thick welds. For example, flux consumption may be as much as 0.5 kg per 10 kg (1 lb per 20 lb) of deposited metal for welding 38 mm (1½-in.) thick plates, decreasing to 0.5 kg per 35 kg (1 lb per 80 lb) of weld for thicknesses of 100 mm (4 in.) or more. To maintain a constant depth of the slag bath as the weld progresses, incremental additions of dry flux must be provided.

Most ESW is accomplished with solid wire electrodes. Tubular composite wires, similar in construction to the flux cored wires previously described, sometimes are found useful for providing the needed flux additions. More often, tubular filler metals are used for welding of low-alloy steels, the alloying ingredients being incorporated as ferroalloys in the core.

Fluxes for Electrogas Welding

Electrogas welding (EGW) resembles ESW in that the weld is done vertically and moves upward, confined by movable copper shoes (Althouse et al. 1997). It differs from ESW in that a shielding gas is used, either a solid or a flux cored wire is fed automatically into the weld joint, and an electric arc is maintained continuously between the electrode and the weld pool. The flux cored wires are similar in construction to those previously described and use the same minerals to protect the arc and to form a slag. They differ principally in the amount of core ingredients because only a very small amount of slag is needed to protect the solidifying metal that forms on the exterior surfaces of the weld joint.

Specification Requirements for Minerals used in Welding Fluxes

Producers of covered electrodes, SAW fluxes, and flux cored wires for carbon and low-alloy steels are constrained by industry specifications that, in particular, limit the sulfur and phosphorus content of the weld metal. For nickel alloys, sulfur is especially harmful, and care is required in the selection of minerals used in electrode coverings and fluxes. Table 5 lists the specifications for many of

the ingredients used in welding fluxes, with particular attention given to specifications commonly imposed on sulfur and phosphorus contents.

Prospective Usage of Minerals for Welding Fluxes

The shielded metal arc welding process has dominated arc welding filler metal production for most of the past century. In terms of minerals use, coverings for electrodes represent the greatest proportion of total minerals used in all arc welding processes. Until the advent of the gas metal arc process in the 1950s (which uses no minerals and thus is not covered in this chapter) and the flux cored arc process in the 1960s, arc welding by covered electrodes represented well more than 60% of all arc welding filler metals. The growth of gas metal arc welding and flux cored arc welding processes, operated both automatically and manually, provided the flexibility that manual welding with covered electrodes had previously. Because both processes use electrodes supplied as coils, they can operate continuously, eliminating the need to interrupt the arc to change individual, separate electrode rods. In recent decades, covered electrodes have declined in volume of welding filler metals to less than 40% in the United States. This is offset, in part, by the growth of arc welding processes worldwide. Even though SAW and other flux-shielding processes use as large an amount of mineral ingredients for each unit of weld as covered electrode welding, their total proportion of the filler metal world market is less than 15%.

Health and Safety

Although arc welding is considered to be a safe occupation, it has potential harmful effects. Welders and operators must wear helmets with eye protection and guard against skin damage from radiation. The welder must be aware of the safe use of electrical equipment and also must avoid fumes evolving from the arc for some metals. This last item has been given considerable emphasis in the last 30 years as a result of litigation and efforts of industrial hygienists and government safety enforcement agencies. The evolution of manganese fumes from welding ordinary steels and certain alloys containing high manganese are of particular concern. Welding stainless steels results in the evolution of chromium fumes, especially the hexavalent form, and to a lesser extent, nickel fumes. Employers in the United States are instructed to provide protection by taking cognizance of the American National Standards Institute (ANSI) Standard Z49.1 (ANSI 1999), and the American Welding Society (AWS) Safety and Health Fact Sheets (AWS 2003).

FLUXES USED IN BRAZING

Brazing is a high-temperature joining process that takes place above 450°C (840°F) but below the melting point of either of the two parent materials that are being joined. A permanent metallurgical bond results when a molten BFM flows, by capillary action, into the closely fitting space between the two metals (brazing joint or gap) and then alloys with (i.e., diffuses into) each of the parent metals, to form a strong, leak-tight, permanent joint. A properly brazed joint will be as strong as, or stronger than, either of the parent materials being joined. In the twenty-first century, both metals and ceramics commonly are brazed. Brazing of ceramics is done primarily in either a vacuum or in inert gas atmospheres and is not discussed here because fluxes are not used in those processes.

Brazing is distinguished from other metallurgical methods of joining. If the temperature is lower than 450°C (840°F), the joining process is known as soldering, and if the temperatures are high enough to melt the parent materials, the process is known as welding.

Table 5. Specifications for welding flux components*

Minerals	Specification		
	Sulfur, % max [†]	Phosphorus, % max	Others, %
Aluminum oxide			Al ₂ O ₃ , 85 min [‡] ; TiO ₂ , 6 max; SiO ₂ , 8 max
Barium fluoride	0.10	0.01	BaF ₂ , 98 min
Cryolite	0.10	0.09	Na ₃ AlF ₆ , 96 min
Fluorspar	0.10	0.02	CaF ₂ , 96 min
Ilmenite	0.10	0.10	TiO ₂ , 65; Fe ₂ O ₃ , 30; SiO ₂ , 0.4 (typical)
Iron oxide (magnetite)	0.10	0.05	Fe, 65 min; Mn, 1.0 max; SiO ₂ , 1.0 max
Limestone			CaCO ₃ , 90; MgCO ₃ , 6; Other 4 (typical)
Lithium fluoride	0.15		LiF, 97 min; Fe, 1 max
Magnesium carbonate	0.02	0.02	MgCO ₃ , 92 min; SiO ₂ , 4 max; CaO, 1.5 max
Magnesium oxide	0.03	0.03	MgO, 96 min; Fe ₂ O ₃ , 1.5 max; Al ₂ O ₃ , 1 max; CaO, 1.5 max; SiO ₂ , 1 max
Manganese oxide	0.10	0.15	MnO, 79 min; SiO ₂ , 8 max; Al ₂ O ₃ , 8 max
Manganese carbonate	0.25		MnCO ₃ , 90 min
Nepheline syenite			Na ₂ O, 15 min; TiO ₂ , 34 min; MnO, 20 min; SiO ₂ , 15 min
Potassium manganese titanate			TiO ₂ , 35; K ₂ O, 26; MnO, 18; SiO ₂ , 15 (typical)
Potassium titanate	0.10	0.10	TiO ₂ , 66; K ₂ O, 25; SiO ₂ , 6 (typical)
Rutile	0.02	0.03	TiO ₂ , 92 min; ZrO ₂ , 2.5 max; SiO ₂ , 2.5 max
Silica sand	0.03	0.03	SiO ₂ , 98 min
Sodium fluoride			NaF, 97 min
Sodium manganese titanate			Na ₂ O, 15 min; TiO ₂ , 34 min; MnO, 20 min; SiO ₂ , 15 min
Sodium silica titanate			Na ₂ O, 20; SiO ₂ , 20; TiO ₂ , 60 (typical)
Strontium carbonate	0.10		SrCO ₃ , 96 min; BaCO ₃ , 2 max; CaCO ₃ , 1 max
Strontium fluoride	0.20	0.03	SrF ₂ , 96 min; BaF ₂ , 2.5 max
Zircon	0.06	0.07	ZrO ₂ , 65 min; SiO ₂ , 34 max

* Blank cells indicate that the mineral is not normally specified by users because commercial supplies rarely contain significant amounts.

[†] max = maximum.

[‡] min = minimum.

As metals are heated, they tend to react more readily with oxygen, forming oxides on the surfaces to be joined; this can prevent complete brazing from occurring. Two ways to prevent the occurrence of such surface oxidation during brazing are: (1) to heat the parts in an atmosphere in which there is no oxygen (such as in a vacuum, or in dry hydrogen, nitrogen, or argon); (2) to coat the surfaces to be brazed with a flux.

Role of Minerals in Brazing Fluxes

For the BFM to spread completely over the surfaces to be brazed, the surfaces must be cleaned completely and free of oil, dirt, grease, or oxides before the flux is applied. A flux is designed to keep the brazing surfaces clean and free of oxides during the brazing process. Fluxes react with any oxides formed on the metal surface during heating to remove those oxides and free up the metal surface to receive and alloy with a molten BFM. When surfaces to be brazed are cleaned properly, the BFM is said to “wet” (i.e., alloy with) and flow over those surfaces effectively. A good flux helps to make that happen whenever the brazing process occurs in an atmosphere that contains oxygen (e.g., torch brazing in air).

BFMs range widely in composition. They can be pure copper; complex alloys of aluminum; precious metals (silver, gold, or platinum); or nickel-based alloy systems. Each requires a different type of flux because the temperature at which the fluxes need to be active depends on the BFM system being used. Fluxes for aluminum brazing need to become active in the 475°C (900°F) range and fully active by 540°C (1,000°F), whereas some of the nickel-based

Table 6. Requirements for commercial brazing fluxes

AWS Class	Base Metal Used on	Temperature Range
FB1	Aluminum	540–615°C (1,000–1,140°F)
FB2	Magnesium	480–620°C (900–1,150°F)
FB3	Steel, copper, stainless steel	565–1,200°C (1,050–2,200°F)
FB4	Base metals with some Al, Ti	600–870°C (1,100–1,600°F)

Adapted from AWS 1992.

BFMs require fluxes that are most active at temperatures higher than 1,100°C (2,000°F). Brazing done with silver-based BFMs requires fluxes that are most active in the 500° to 900°C (1,000° to 1,600°F) range. See the *Brazing Handbook* (AWS 1991b) for a more thorough discussion of brazing, brazing filler metals, and brazing techniques.

Constituents of Brazing Fluxes

As mixtures of various minerals, flux formulations vary considerably because, as mentioned, they are designed to become “active” within different temperature ranges, depending on the type of BFM used. The AWS *Specification for Fluxes for Brazing and Braze Welding* (A5.31), which is used widely in industry, has changed completely the previous AWS flux designations (AWS 1992). Most commercial brazing fluxes in present use meet the current requirements of this specification (Table 6).

The minerals and compounds used in making the fluxes listed in Table 6 usually include one or more of the following (AWS 1991a):

- Borates (sodium, potassium, lithium, etc.)
- Fused borax
- Elemental boron
- Fluorides (sodium, potassium, lithium, etc.)
- Chlorides (sodium, potassium, lithium, etc.)
- Alkalis (sodium hydroxide, potassium hydroxide)

Borates

Borates, such as potassium tetraborate ($K_2B_4O_7 \cdot 4H_2O$), are used in high-temperature fluxes because they effectively can reduce oxides at temperatures around 760°C (1,400°F) and higher. Because they are quite viscous when molten, they usually are mixed with other mineral salts to lower their viscosity so that they will flow easier into the brazing joints.

Fluoborates flow well on metal surfaces and have excellent oxide-dissolving properties.

Fused Borax

Fused borax ($Na_2B_4O_7$) is used in high-temperature fluxes because it will also reduce oxides at higher temperatures.

Elemental Boron

Finely powdered boron is added to other flux chemistries to give them greater fluxing ability for higher-temperature applications and to last over longer periods.

Fluorides

Fluorides, such as potassium fluoride (KF), very aggressively reduce metal oxides and so are used in fluxes for metals containing refractory oxides of chromium and aluminum. They also increase the fluidity of the fluxes in the molten state.

Chlorides

Chlorides, such as potassium chloride (KCl), are similar to fluoride fluxes in their use, but are more effective at lower temperatures.

Alkalis

Alkalis are used sparingly because of their water-absorbing properties; however, alkali compounds, such as potassium hydroxide ($K(OH)_2$) and sodium hydroxide ($Na(OH)_2$), help to elevate the useful working temperature of the flux. Because of the tenacious nature of the oxides of aluminum, titanium, and zirconium, and because of the lower temperatures used in brazing aluminum, specialized fluxes consisting of mixtures of alkali metal chlorides and potassium or lithium fluoride are used in brazing these metals. A reaction flux containing 7% to 12% by weight of zinc chloride is helpful in brazing aluminum because of the difficulty in removing the aluminum oxide layer between the brazing surfaces.

Sources of Minerals for Use in Brazing Fluxes

Boron minerals and compounds, such as borax ($Na_2B_4O_7 \cdot 10H_2O$), boric acid (H_3BO_3), and potassium borate, are produced mainly in Southern California (primarily in the Death Valley region), Turkey (the world's largest producer), Chile, and Russia. Industrial boron compounds are recovered from both crude and refined sodium borates, from anhydrous derivatives, and from anhydrous boric acid. The largest domestic boron minerals producer operates open pit mines for tinical (crude borax) and kernite ($Na_2B_4O_7 \cdot 4H_2O$). Other producers in the same area recover potash in addition to boric acid

and other boron products by differential evaporation and solvent extraction methods from saline brines. Total U.S. production of boric oxide in 2003 amounted to approximately 536,000 t, valued at about \$275 million (Lyday 2004a).

Fluorides

The primary fluorine compounds used in fluxes for brazing include aluminum fluorides, potassium fluoride, and lithium fluoride. Major sources of fluorine are fluorite (CaF_2) in fluorspar deposits and the mineral fluorapatite, which occurs in natural phosphate rock (Fulton and Montgomery 1994). China is the world's most important producer of fluorspar (Lyday 2004b). At the present time no fluorspar is being mined in the United States, although the United States is a major producer of phosphate rock and thus of fluoro-silicic acid.

Hydrofluoric acid (HF) is made when acid grade fluorite (97% CaF_2) is reacted with sulfuric acid in a heated kiln or retort. Elemental fluorine, prepared from anhydrous hydrofluoric acid by electrolysis, reacts with all metals to form fluorides, including artificial cryolite (Na_3AlF_6), aluminum fluoride, potassium fluoride, and other inorganic fluorine compounds. Fluorosilicic acid is produced during the processing of phosphate rock, and some is converted to aluminum fluoride and cryolite.

A rapidly growing part of the aerospace/brazing industry involves the high-temperature cleaning of aerospace jet engine components in special furnaces using anhydrous hydrogen fluoride gas.

Chlorides

Practically all of the chlorine and chlorine compounds made in the United States are produced by electrolysis from sodium chloride solutions. Sodium chloride, salt or the mineral halite ($NaCl$), occurs in sea water, salt lakes, and in extensive beds of rock salt. A common mineral, halite is produced by either mining salt beds or by solar evaporation of brines in many domestic locations, including New York, Michigan, Louisiana, Utah, and other states. Potassium chloride, the mineral sylvite, occurs in salt deposits in New Mexico and Saskatchewan, and in several European and Asiatic locations.

Chlorine reacts readily with hydrogen to form hydrochloric acid; both chlorine and hydrochloric acid react with most metals to form chlorides. Hydrated aluminum chloride ($AlCl_3 \cdot 6H_2O$) is formed when aluminum hydroxide reacts with hydrochloric acid. Ammonium chloride (NH_4Cl) is formed as a byproduct from the reaction of gaseous ammonia with hydrogen chloride gas or by the reaction of ammonium hydroxide with hydrochloric acid.

In the United States, spodumene deposits in North Carolina and geothermal brines in Nevada supply the raw materials for the manufacture of lithium compounds, such as lithium chloride ($LiCl$). Lithium carbonate is the primary product of lithium chemical plants and is the compound from which all other downstream lithium products are obtained.

Cesium-based Flux Compounds

Cesium, in the forms of cesium chloride, cesium fluoride, or cesium aluminum fluoride, has been used on an experimental basis as a component of some general purpose fluxes, but such use has not met with widespread acceptance because of the high cost of cesium compounds.

ACKNOWLEDGMENTS

The section on fusion welding was written by R. David Thomas, and the section on brazing was written by Dan Kay. Kay wishes to express his gratitude to James Watson Baxter, author of the Fluxes

in Soldering, Brazing, and Welding chapter in *Industrial Minerals and Rocks*, 6th edition. This chapter on brazing is a revised and updated version of his work, with the omission of the section on soldering.

Foundry Sands

Stanley T. Krukowski

INTRODUCTION

Foundry sands, which are used to make molds and cores, have been very important to foundry workers since metal casting began hundreds of years ago. They now are used in two basic ways, either in a natural state bonded with clay or in a chemically cured state achieved with sand that, mixed with chemical resin or oil, is cured by baking or by chemical reaction.

The term *sand*, as used in foundry applications, can best be defined as material composed of granular particles of mineral matter ranging from 0.5 to 2.0 mm in diameter. Based on their origin, raw materials for foundry sand vary in grain shape, grain composition, relative surface, grain size, and grain distribution patterns. These properties, in addition to chemical analyses, sinter point, and expansion characteristics, play an important part in the choice of sand used as the base molding or core aggregate in metal casting. Different types of sand may be blended to produce specific compositions and grain size distributions.

Early raw material requirements based on silica sand were simple, but as sand/core/mold technology became more sophisticated and binder technology developed further, the physical properties of foundry sand became more critical. Silica sand is mainly quartz and, in most cases, small amounts of feldspar, mica, clay, and other common minerals. Although silica sand is still by far the most widely used base material in production of molds and cores used in metal casting, other natural mineral sands have their own unique characteristics and fill an important niche in special applications. As a result, the term *sand*, when applied to raw materials used in metal casting, logically has been extended to include granular materials composed of a group of minerals other than quartz. With increased use in advanced foundry technology, natural sands composed predominantly of zircon, chromite, staurolite, or olivine have become more than just alternate materials and now are classified commonly as sands. Therefore, foundry sands can be divided into two categories: silica sands and non-silica sands.

SILICA SANDS

Silica is the common term applied to silicon dioxide (SiO_2); the mineral name is quartz. The term *sand* has two different meanings, depending on the context in which it is used. In context of mineral composition or rock type, the term usually is understood to refer to unconsolidated quartz grains within a certain range of grain size.

In ancient rocks, granular particles (sand grains) have become cemented together to form a consolidated sedimentary rock referred to as sandstone. The term sand also is included in a continuum of particle sizes that includes other terms denoting size classification from finest to coarsest (in diameter): clay (< 0.0039 or $1/256$ mm), silt (0.0039 to 0.0625 or $1/16$ mm), sand (0.0625 to 2.0 mm), granule (2.0 to 4.0 mm), pebble (4.0 to 64.0 mm), cobble (64.0 to 256.0 mm), and boulder (> 256.0 mm).

The most common foundry sand used over the years has been silica sand. It is common, abundant, and easily mined, occurring at or very near the earth's surface. Silica sands are produced from rocks that formed under a variety of geologic conditions and are used in a number of industrial applications other than foundry sands: sand blast abrasives, fillers, glass manufacture, oil and gas proppants, refractories, and as a source of silicon.

Modes of Occurrence

Silica sand deposits occur naturally as a result of weathering and erosion of quartz-bearing igneous, metamorphic, and sedimentary rocks. The products generated from these processes are subsequently transported to the site of deposition. Disaggregated rock and mineral particles may be carried hundreds of kilometers from their source(s) by fluvial, glacial, glacioluvial, marine, and eolian processes. The composition of deposits depends on the nature of the original rocks that were eroded, the intensity and duration of weathering, the distance and agents of transportation, the manner of deposition, and postdepositional history. Deposits may be reworked by natural processes and redeposited under similar or entirely different conditions.

Silica sands accumulate along stream channels and floodplains, in lake and lakeshore deposits, and under marine conditions in seacoast environments. Geologically young deposits tend to be unconsolidated or poorly consolidated. Ancient sand bodies, which were buried under great thicknesses of younger sediments and later consolidated, are termed *sandstone*. Subsequent uplift from tectonic forces can stop sedimentation and begin widespread erosion and exhumation of previously deeply buried formations. Those that are exposed at the surface, or that have only a thin layer of overburden, can readily be mined. Cycles of repeated weathering, erosion, transportation, sorting, and deposition result in well-sorted, high-purity, quartz sandstone from which practically all heavy minerals have been eliminated.

Figure 1. Thermal expansion of silica materials

Advantages and Disadvantages

Silica sand has the advantages of common occurrence and abundance, ease of bonding with organic or inorganic binders, low cost, and the ability to be reclaimed for reuse by wet, dry, or thermal methods. It also possesses certain disadvantages when used in the production of metal castings. The major disadvantage of silica sand is its characteristic high thermal expansion. This expansion causes casting quality problems and contributes to other expansion-related defects. Figure 1 illustrates the typical thermal expansion of various silica materials and depicts alpha quartz, the characteristic polymorph of silica sand, expanding at a constant rate until it reaches a temperature of approximately 573°C. As the temperature increases beyond this point, a sudden expansion takes place because of the change from alpha quartz to beta quartz. High thermal expansion requires carefully controlled additions of cushioning materials (e.g., cellulose additives) to minimize the deformation and rupture of mold surfaces in contact with molten metal. Another disadvantage is that silica sand is unable to resist metal penetration and reactions that occur in quartz when in contact with casting surfaces. These problems arise where there are reentrant angles in hot-spot areas of large iron and steel castings and, in Hadfield's austenitic manganese steel castings, when the steel contains high amounts of manganese that attack (or wet) the silica sand mold surfaces.

Classification of Silica Sands

Silica sands used in foundry practice vary in grain size distribution (Table 1), purity, structure, grain shape, and refractoriness.

Unbonded sands, which often are referred to as washed and dried silica sands, are found in many areas of the United States. Analyses of typical silica sands are shown in the top rows in Table 1. Major production in the Midwest and midcontinent comes from the St. Peter Sandstone and its stratigraphic equivalents. Medium- and fine-grade washed sands are produced in the East, particularly in Cumberland County, New Jersey. Silica sands from Nevada have been shipped to West Coast foundries. For additional sources of silica sand, refer to the chapter on industrial sand and sandstone in this volume.

Processing

Washed, graded, and dried (clay-free) silica sands are prepared for use in casting production by bonding them with required amounts of binders, additives, and necessary amounts of temper water. The

total sand mixture is prepared in the sand muller to achieve uniform distribution and dispersion of clay and additives over and around individual sand grains.

Foundry Use

Medium-grade sands are used predominantly for casting steel and heavy, gray, ductile iron; fine-grade eastern silica sand is used in making precision castings (Henderson 1983). The St. Peter Sandstone is a popular product when washed and dried because its round grain shape promotes flow and its smooth grains require less bonding material.

Bank Sands

Unconsolidated deposits with relatively small clay content (less than 5%), requiring little processing beyond drying and scalping, still are referred to as *bank sands*, although they usually are subjected to considerable processing and blending before shipment. These bank sands are sedimentary in origin and vary in purity depending on the amount of minerals and foreign materials that they contain. In many areas they have high purity and are suitable for foundry use. Table 1 shows a typical analysis of fine bank sand from New York.

Processing. Bank sands are hauled to the plant after stripping. A front-end loader dumps the sand into a hopper, and then it is conveyed to a rotary screen with 12.7-mm openings to remove roots and other organic debris. Some screened sand is dried and shipped without further processing because it meets the specifications for a system sand addition and for synthetic sand base; some is washed to produce a cleaner, more consistent product.

The sand is dropped into a surge bin to ensure a uniform feed and for subsequent washing. It is then conveyed to a tank where it is mixed with water and pumped to a scalping screen where fine roots and other organic materials are removed. Scalped sand is pumped to a deslimer to remove clay and silt, fresh water is added, and the sand slurry is either pumped to a second deslimer before going to ground storage or fed to banks of screens and separated further into fine and coarse particle sizes. Each sand grade is collected in a sump, mixed with water, pumped to a deslimer and dewatering cyclone, and stockpiled for drainage and storage. Then the sand is dried, cooled, and passed over a final scalping screen before it is conveyed to storage bins before shipment.

Foundry Use. Fine bank sand is used as a base for molding sand in medium- to small-sized, gray iron castings typical of those used in casting hardware and hand tools and for casting aluminum and copper-based alloys (Henderson 1983).

Lake Sands

The term *lake sands* refers to sands dredged from Lake Michigan or dug from dunes bordering its shore; although the dune sands were shifted by wind, they still are considered a part of the lake-sand deposit. During deposition, some natural sorting by grain size, grain composition, and specific gravity can occur. Table 1 shows a typical size analysis of lake sand. The degree of purity is the result of geologic processes and history.

Processing. In a typical lake-sand operation, overburden is stripped and a front-end loader mines the sand and feeds a hopper that discharges to a portable screen where deleterious material is removed. The hopper and screen can be moved along a field conveyor as required. Conveyor belts transport sand to the plant site for further processing or blending.

Foundry Use. Lake sands in large quantities are used in the production of automotive and farm machinery castings (Henderson 1983).

* AFS = American Foundry Society.

Consumption of Silica Sands

About 27.5 Mt of industrial sand and gravel were sold or used in the United States in 2003 (Dolley 2003). Of this total, more than 19% (5.225 Mt) was molding and core sand and refractory sand. Refractory sand accounted for only 3.25% of the total foundry sand sold or used. About 83% of the foundry sand was produced in the Midwest.

NONSILICA SANDS (AGGREGATES)

Continued demand for improved cast surfaces and closer dimensional tolerances has revealed some of the physical and chemical limitations of silica sands. Specialty sands composed of materials other than silica possess properties that make them superior to silica sand for certain applications.

Nonsilica aggregates (zircon sand, chromite sand, and olivine sand) have gained wide acceptance and are used throughout the metal-casting industry for their desirable properties. Nonsilica molding media such as aluminum silicate sand and staurolite sand also possess unique properties, but their use in casting production has been on a smaller scale. Table 2 shows some of the typical properties of the nonsilica sands compared to silica sand.

Nonsilica aggregates have much lower rates of thermal expansion than silica sand (Figure 2), and their rates of expansion on heating are not affected by phase-change relationships like

those exhibited by quartz. Expansion-type defects are greatly reduced or, in many cases, eliminated when major nonsilica minerals are used.

Zircon Sand

Sources

Major sources of zircon ($ZrSiO_4$) sand are heavy mineral sands in Australia (east and west coasts), Brazil, India, Sierra Leone, Republic of South Africa, and the United States (north-central Florida). Heavy mineral suites commonly consist of ilmenite, leucosine, tourmaline, spine l, kyanite, sillimanite, corundum, topaz, zircon, and staurolite. The primary products mined from these heavy mineral sands are titanium-bearing minerals. Zircon, staurolite, and aluminum silicate minerals are valuable by-products for use in foundry practices.

Mining and Concentration

The following describes a typical mining operation in a marine, dunal shoreline deposit in the southeastern United States. After stripping, a suction dredge recovers sand at up to 1,000 t or more per hour. The sand, which contains about 4% heavy minerals, is pumped to a floating wet mill where it undergoes three stages of gravity concentration using spiral separators. The wet mill produces

a concentrate averaging 85% heavy minerals with an 80% recovery. The concentrate is pumped to a land-based dry mill where the scrubbed ore is dried before undergoing various magnetic and electrostatic separations that remove titanium-bearing minerals. Tailings from the titanium separations are fed to high-intensity magnetic separators to produce a variety of by-products; zircon is the major constituent of the nonmagnetic, nonconductive fraction.

Properties

Zircon sand possesses most of the desirable properties for foundry sand, including chemical and thermal stability. The major advantages of zircon sand are

- Lowest thermal expansion of any foundry sand
- High thermal conductivity and high bulk density, which are responsible for a cooling rate approximately four times that of quartz
- Completely unwetted by molten metal
- Chemically nonreactive
- Less binder required than any other foundry sand when using chemical binders
- Compatible with all known binder systems (organic or inorganic)
- Excellent dimensional and thermal stability characteristics at elevated temperature
- pH neutral or only slightly acid

Foundry Use

Zircon sand is used as a molding medium and as core sand. When finely ground and combined with a suspending agent and a binder, zircon is employed widely as a refractory in the manufacture of core and mold washes.

Chromite Sand

Sources

The element chromium (Cr) combines with iron (Fe), magnesium (Mg), calcium (Ca), lead (Pb), copper (Cu), phosphorus (P), and sulfur (S) to form a variety of minerals. Of these, chromite (FeCr_2O_4) is the only metallic ore mineral of chromium and the only source of chromium compounds, chemicals, and foundry sand. In 2003, the International Chromium Development Association (ICDA) reported that 91.2% of the world production of chromite

ore (14.868 Mt) was consumed in metallurgy, 5.2% in chemicals, 2.8% in foundry sand, and 0.8% in refractories (Papp 2003).

Most of the world's production of chromite ore comes from South Africa, which accounts for 48%. Kazakhstan and India account for 19% and 15%, respectively. Brazil, Finland, Turkey, and Zimbabwe represent 12% of world production, and 12 other countries produce the remaining 6% (ICDA 2005). The United States has a small amount of chromite ore reserves, but more than 92% of the material has relatively high Fe and low Cr content. The reader is referred to the chapter on chromium in this volume for more detailed information.

Mining and Milling

Chromite deposits are associated with the basic igneous rocks peridotite and pyroxenite, or with serpentine resulting from the alteration of the se rocks. Most South African mines extend underground. Ore is drilled, blasted, loaded onto conveyors or mine cars, and hauled to a processing plant. Hand sorting or mechanical screening separates lumps and chips from the sand, followed in some cases by bar or rod milling to reduce the sand to American Foundry Society grain fineness number (AFS GFN) 80, and to release the gangue minerals (primarily serpentine and talc). The natural grain size of approximately AFS GFN 55 is preferred for metal casting. Chromite sand is beneficiated further by auger-type washers to remove slimes and by gravity concentration using riffling tables or spiral separators. Then the sand is stored on concrete pads where it is allowed to drain. The sand, which must contain a minimum of 45% Cr₂O₃, is assayed at this point. A turbidity test has been developed to control washing processes and to ensure production of clean sand. The sand is hauled by truck or rail before it is shipped to the United States or other places.

Finishing

At finishing plants in the United States, chromite sand is beneficiated by drying, cooling, and screening to produce grades ranging from AFS GFN 55 to 80. The sand may be washed further to less than 150 ppm turbidity for certain core operations. Quality control tests include turbidity, acid demand values (ADV), and sieve and chemical analyses.

Properties

Chromite sand was introduced to the foundry industry in the early 1960s when zircon sand was in short supply. Later, when zircon sand prices were rising, foundry workers adapted chromite sand as a substitute for zircon sand. Chromite sand is successful as nonsilica foundry sand because of its following properties:

- Excellent thermal stability
- Good heat-diffusivity characteristics
- Not easily wetted by molten metals
- Highly refractory
- Chemically nonreactive
- Low thermal-expansion coefficient

One of the major disadvantages in using chromite sand is the presence of hydrous impurities that can contribute to pinholing and blows.

Foundry Use

Properties of chromite sand, shown in Table 2, specifically fulfill some of the extreme thermal requirements of heavy, sectioned, ferrous castings. In addition, the basic nature of chromite sand makes it highly desirable when producing castings of Hadfield's austenitic manganese steel.

Olivine Sand

Sources

Olivine is a magnesium-iron silicate mineral, (MgFe)₂SiO₄. Olivine sand is produced from dunite, a rock composed predominantly of olivine. Large deposits of dunite are found in Norway, Sweden, the Commonwealth of Independent States (CIS), Austria, Zimbabwe, South Africa, and the United States. Norway is the principal producer and supplier of olivine. Additional producers include Australia, Austria, Brazil, China, Italy, Japan, the Republic of Korea, Mexico, Spain, Taiwan, Turkey, and the United States. Deposits in Washington and North Carolina furnish major amounts of olivine sand for foundry use in the United States; processing plants are located in Indiana, North Carolina, and Washington (Kramer 2004).

Mining and Milling

Olivine mining is by open-pit methods in the United States. After blasting, a drop ball breaks large lumps into particles 2 ft or smaller. Ore passes through a primary jaw crusher where it is reduced to 15 cm or smaller before it is fed to the processing plant. At the mill, the rock is reduced further to 12.7-mm particles by jaw and gyratory crushers. It then passes through a screw classifier that washes out clays and slimes. A rod mill then reduces the olivine to sand size before it is pumped to scalping screens. Oversized material returns to the rod mill and undersized material is fed to riffling tables for gravity separation of olivine from gangue, which is predominantly serpentine and talc. Tables are fed slurry of 25% solids and more water is added. Product quality is controlled by the amount of water used, the tilt of the tables, and reciprocating speeds. Olivine concentrate, representing 60% of the table feed, is pumped to a dewatering screen and then to dewatering tanks. The sand is dried before screening to produce a variety of size grades.

Properties

Olivine sand is less stable under thermal shock conditions than zircon sand or chromite sand, but its thermal expansion is much less than silica sand. The presence of hydrous magnesium silicates (serpentine) may contribute to pinholing or pock marking when olivine sand (uncalcined) is used in the production of low carbon steel castings. Olivine sand particles are less durable than other nonsilica sands, although it has comparable hardness. This may be attributed to olivine's cleavages and other physical or chemical characteristics. Olivine still has good refractory properties plus lower free silica content and strong resistance to metal attack.

Foundry Use

Olivine sand has been very successful in nonferrous casting as well as ferrous casting production where high thermal requirements are not necessary. Olivine sand is an excellent substitute for silica foundry sand, particularly for molding sand for aluminum, bronze, copper, manganese steel, gray iron, and alloy steel. Additionally, olivine's low basicity enhances bentonite's bonding properties so that clay demand is reduced (Harben 2002). The basic characteristics of olivine also make it an ideal aggregate for the production of castings of Hadfield's austenitic manganese steel.

Aluminum Silicate Sand

Sources

Along with zircon sand, aluminum silicate is a by-product of mining titaniferous, heavy mineral, beach sands. Those mined in Florida contain significant quantities of kyanite, sillimanite, and andalusite. The Republic of South Africa, the United States, France, and India account for up to 98% of worldwide sillimanite

production; andalusite production is dominated by the Republic of South Africa, France, and Spain; kyanite production comes mainly from the United States and India (Harben 2002).

Mining and Concentration

Mining and concentrating Florida beach sands and processing the various heavy mineral products were discussed briefly in the section on zircon sands. To concentrate the aluminum silicates, additional processing is required, removing contaminants, dust, and other fines by scrubbing and washing the heavy mineral sand. Intensive magnetic and electrostatic separation produces rounded-grain sand.

Properties

In terms of mineralogy, the aluminum silicate minerals, kyanite, sillimanite, and andalusite, are similar; all have the same chemical composition (Al_2SiO_5). In addition, all three are thermally stable up to $1,810^\circ\text{C}$. At that temperature they break down to yield 88% mullite ($\sim\text{Al}_6\text{Si}_3\text{O}_{15}$) and 12% free silica (cristobalite). Mullite has the following desirable characteristics:

- High refractoriness
- Low thermal expansion
- Resistance to thermal shock
- Intermediate thermal conductivity
- Resistance to chemical erosion

Foundry Use

Because of its neutral character, aluminum silicate sands have been successful in producing Hadfield's austenitic manganese steel and other ferrous castings. These nonsilica sands are also compatible with all known binder systems.

Staurolite Sand

Sources

Staurolite occurs naturally as a mineral with the general formula $(\text{FeAl}_5\text{Si}_2\text{O}_{12})(\text{OH})$. Staurolite sand is produced in the southeastern United States as a by-product of heavy mineral operations that also yield zircon sand and aluminum silicate sands.

Mining and Concentration

Staurolite and other heavy minerals are removed from heavy mineral sand after dredging by concentrating them in three stages of spiral separators on a floating wet mill. Then the heavy mineral concentrates are pumped to a conditioning unit where they are scrubbed with caustic to remove organic and clay coatings from grain surfaces. The heavy mineral sands are rinsed and dried; electrostatic and magnetic separation concentrates the staurolite. This magnetic, nonconductive product used for foundry sand consists principally of staurolite with small percentages of tourmaline, spinel, and silicates with magnetic inclusions as impurities.

Properties

Staurolite sand for casting production possesses the following favorable properties:

- Low thermal expansion
- High melting temperature
- Low silica content
- High thermal conductivity
- Suitable refractoriness

- Durability
- Compatibility with various binder systems

Although staurolite sand's thermal expansion is slightly greater than that of zircon sand or chromite sand, it is approximately equal to that of aluminum silicate sand and olivine sand (depicted in Figure 2).

Foundry Use

Staurolite sand has been used as base aggregate or blended with silica sands in the production of nonferrous castings and ferrous castings of light to medium section thickness. Because of its lower melting point at approximately $1,538^\circ\text{C}$, staurolite is not recommended for use in steel casting production.

Overall Benefits from Nonsilica Sands

Increasingly complex castings present the foundry worker with problems of design and geometry, so it is becoming more critical that workers plan to use special aggregates for molds and cores. Judicious use of various nonsilica sands can minimize problems in casting quality. Their use results in costs savings in finishing, which improves quality of the casting surface.

ECONOMIC FACTORS

Most economic factors related to production and processing of foundry sands raw materials are covered in the commodity chapters of this volume; some of these factors are discussed here. Most of this discussion involves silica sand.

Consumption

In 2003, industrial sand and gravel (silica sand) in the United States amounted to 27.5 Mt sold or used; 19% of that production was accounted for by the foundry industry. In the United States, minable resources are relatively common and abundant so that mining companies can easily locate their operations near their markets. Manufacturers traditionally locate their operations close to the source of raw materials. The U.S. automotive industry is an example. Factories originally were located in the Midwest where abundant clay, coal, iron, limestone, and silica resources occur. Consequently, foundry sands have been produced widely in Illinois, Indiana, Michigan, Ohio, and other midwestern states. In 2003, more than 83% of foundry sand was produced in the Midwest (Dolley 2003).

Consumption of foundry sand is closely tied into the manufacturing sector of the economy. It stands to reason, therefore, that when the economy is healthy, the consumption of foundry sand should increase; likewise, during economic downturns, consumption of foundry sand would decrease. Demand, production, and use of silica sand reflect the overall economic trend, but to some extent the substitution of nonsilica foundry sand also may play a role in silica foundry sand consumption.

In 1984, the U.S. foundry industry comprised 3,400 foundries; in 2004, there were just 2,380, which meant a loss of more than 1,000 businesses and a contraction of almost 30%. More than 50 foundries have been lost every year for the past 20 years. Despite some new and expanded facilities, it was estimated, based on 2001 production, that a loss of casting supply of 225,000 t was to occur in 2004 (AFS 2005).

Price

In 2003, ground sand for foundry molding and core had the highest average price of industrial sand and gravel at \$85.29/t. The average value of refractory-grade silica sand was \$39.16/t. The total value of

foundry sands sold or used in 2003 was approximately \$81.8 million; less than 3.25% of that value was attributed to refractory sands.

Transportation

Transportation costs to point of first sale or use have a pronounced effect on the pricing structure of sand products and the viability of deposits. As previously noted by Henderson (1983), because of higher shipping costs, the market price of zircon sand from Florida heavy mineral deposits, in which zircon concentration runs about 1.5%, is comparable to that from Australian sands, some of which run up to 15% zircon.

Of the total industrial sand and gravel produced in 2003, 64% was moved by truck, 35% was moved by rail, and 1.4% was transported by waterway (Dolley 2003). Such statistics for foundry silica sand would, perhaps, be similar. The trend was toward truck haulage and use of pressurized tank trucks when the sixth edition of this volume was written, and indeed that is reflected in the 10% increase from 1990 as reported by Kotzin (1994); oil prices are at near-record highs (greater than \$60 per barrel) at the time of this writing, however, and the trend is to increase shipments by rail.

REGULATORY CONSIDERATIONS

Zoning and Land Uses

Certain permits are required for the installation and operation of sand pits and dredging operations. Provisions for land use and mining permits vary from state to state and differ with respect to private and public land ownership. The following requirements are generic and may be more closely related to silica sand operations in states in the midwestern United States.

Special Use Permit

Many pits and quarries operate in lands zoned for agriculture under a special use permit issued by local zoning agencies. State agencies may not necessarily be involved in this permitting process. Applications submitted to and reviewed by a zoning board may then be referred to the county board of supervisors or similar agency for approval. Some counties require that a copy of the application also be submitted to the local soil and water conservation district, from which a response may be required before the application can proceed.

Mining Permit

A mining permit may be required if the planned operation will disturb more than a prescribed acreage annually, or involve the removal of a specific thickness of overburden. The application ordinarily goes to the state regulatory agency with jurisdiction over mining. An environmental assessment (EA) or environmental impact statement (EIS) usually is required. In some states the application for a mining permit must be filed with the appropriate county clerk concurrently. The county, in some cases, may have a specified length of time in which to respond. If no timely objections are lodged, the permit is issued within some specified time interval. The time period can be extended indefinitely if there are objections and a call for public hearings. Permits usually are for periods of a few years. In some jurisdictions, if no development has occurred during the original life of the permit, an extension may be limited to a fraction of the original acreage.

Construction and Operating Permits

Construction and operating permits generally are necessary. Applications typically are submitted to the state environmental protection

agency or department of environmental quality and may require an EA or EIS.

Dredging Permits

Dredging operations require a permit from the U.S. Army Corps of Engineers and also may require filing with the environmental agency responsible for water quality.

ENVIRONMENTAL CONSIDERATIONS

In 1987, the International Agency for Research on Cancer (IARC) expressed the opinion that crystalline silica (quartz) is probably carcinogenic to humans. This subject is covered in the Industrial Sand and Sandstone chapter in this volume and is not duplicated here.

Water Pollution

Many sand pits and other sources of foundry sand are located in riparian areas, or, in dredging operations, the materials may be derived directly from a wetland area or water body. The mine operator may require large amounts of water for washing or classification of sand products. Sand producers in some western and southwestern states rely on water wells.

Process water often becomes laden with fines and must eventually be discharged back into water courses. Because such operations usually do not use process chemicals, process waters are not affected; water turbidity, however, may be a matter of regulatory scrutiny. Different water clarification methods can be used to restore water quality, and in some cases effluent waters may leave a plant in better condition than when first obtained for processing.

Air Pollution

Stockpiles, roadways, and sand dryers may pose challenges to dust control. Watering roadways, dampening stockpiles, using dust collectors, and using other dust-control measures are common practice in suppressing dust in the mining industry.

FUTURE PROSPECTS

Supply-and-Demand Considerations

The future for molding sand is tied to metals. It has been suggested that consumption of both ferrous and nonferrous metals ceased to grow in about 1960 because of decreasing economic growth rates in the industrialized countries (Davis 1989). Conventional wisdom may indicate that economic recovery at the beginning of the 21st century means better days are ahead; Drucker (1986), however, proposed that U.S. demand for raw materials has been uncoupled from economic growth, implying that economic recovery may not, of itself, result in increased demand for cast metal products and molding sand.

The normal foundry procedure of constructing a mold of sand, clay and other binders, and additives for a single casting can be viewed as extremely inefficient. Burst (1991) proposed that using permanent ceramic molds, with cordierite or other refractory material, could reduce molding sand use in some applications; maintenance of precise dimensions, however, may be a problem as the permanent mold is used.

Future U.S. auto production, augmented by plants being constructed in the United States by foreign automakers, may outweigh such negative factors as increasing use of composites and the development of other lightweight, nonmetallic materials. The nature of the final resolution of the environmental safety issue with respect to crystalline silica will have an immense effect on the future supply-and-demand picture for the various types of foundry sands.

Despite environmental pressures, silica sand will continue to dominate foundry sand practice in the foreseeable future, but it is anticipated that advancements in metallurgy, increased use of light metals, and requirements for more uniform and higher finishes will require increased use of nonsilica sands and the implementation of new technology, some not yet discovered.

The U.S. Geological Survey had forecast that consumption of foundry sand in 2004 would fall within a range of 5 to 6 Mt and probably would be about 5.5 Mt (Dolley 2003). An overall trend toward decreasing production of silica foundry sands is due to increased recycling of foundry sand, additional increases in developing nonsilica substitutes both natural and synthetic, and the decline in casting for automobiles and light-truck production.

Nanomaterials

S. Yeruva, V. Krishna, H. El-Shall, and B. Moudgil

INTRODUCTION

Nanotechnology is engineering aimed at creating structures and materials (with at least one dimension) 1–100 nm long, having unique and potentially useful properties. These nanomaterials have been applied in the aerospace, electronics, and biomedical fields. When the sample size, grain size, or domain size becomes comparable with a specific physical length scale such as the mean free path or the coherence length of phonons, the corresponding physical phenomenon will be strongly affected. Although such changes in behavior can be dominant, their practical implications, except for electronic systems, are not yet realized significantly in industrial scales. Apart from the electronics industry, the only other large-scale application of nanotechnology has been the use of nanoclay as filler material in polymer systems. The combined physical, chemical, and biological aspects of nanoscale systems effectively form a new discipline with its own set of physical principles, experimental techniques, and environmental considerations. The recent advancement witnessed in technology is just a glimpse into the future of nanotechnology.

HISTORY AND BACKGROUND

Nature has been using nanomaterials for millions of years. Examples include DNA and proteins that help in proper functioning of cells (Alberts et al. 2002). Although humankind has been obliviously creating nanoparticles as by-products of combustion for thousands of years, the use of nanomaterials can be found as early as the ninth century in luster potteries (Padovani et al. 2004). The physicist Richard Feynman first laid out the conceptual framework of nanotechnology in 1959, in his lecture titled “There’s Plenty of Room at the Bottom” (Feynman 1960). Feynman explored the possibility of manipulating material at the scale of individual atoms and molecules, foreseeing the increasing ability to examine and control matter at the nanoscale. Norio Taniguchi first coined the term *nanotechnology* in 1974 to refer to the ability to engineer materials precisely at the nanometer level (Taniguchi 1974). The driving force for miniaturization at that time came from the electronics industry, which aimed to produce smaller and thereby faster electronic devices. Nanotechnology has been used to create the tiny features on computer chips for the past 20 years. Many chemical processes have nanoscale features—for example, researchers have been synthesizing nanoparticles, microemulsions, and micelles for decades. It is only in recent years, though, that

sophisticated tools have become available to investigate and manipulate matter at the nanoscale. A major step in this direction was the invention of the scanning tunneling microscope (STM) in 1982 and the atomic force microscope (AFM) in 1986. These tools use nanoscale probes to characterize a surface with atomic resolution. Development of characterization tools not only enhanced the understanding of the nanoscale world but also increased application of nanostructures. The research interest in nanotechnology is increasing worldwide, and is rapidly producing knowledge in this field. In turn, there is a hope that this will lead to dramatic changes in the way that materials, devices, and systems are created, resulting in improved quality of life.

CONCEPTS

Nanotechnology is concerned with materials and systems whose structures and components exhibit novel physical, chemical, or biological properties because of their nanosize. The control of structures at atomic, molecular, and supramolecular scales is desired for efficient fabrication and application of nanostructures. Nanotechnology can broadly be classified into two main areas: (1) particle nanotechnology, where particles are in nanodimensions and exhibit unique properties compared to the bulk, and (2) nanoengineering, where surfaces or devices are engineered in nanodimensions, resulting in unique properties. Nanotechnology emerges from the exploitation of the new properties, phenomena, processes, and functionalities that matter exhibits at intermediate sizes between molecules (~1 nm) and bulk materials (more than 100 nm). As opposed to the microscale, the nanoscale is not just another step toward miniaturization; it results in a qualitatively new material. At nanoscale, material properties are a manifestation of either quantum phenomena or a combination of quantum and classical phenomena.

At nanoscale, increase in surface to bulk ratio of atoms and size confinement produce qualitatively new behavior. When the size of a nanoscale structure becomes less than the characteristic length scale for scattering of electrons or phonons (the mean free path), qualitatively new modes of transport for electrical current and heat are observed (Link and El-Sayed 1999; Prasher 2004). For example, the ballistic transport of electrons is observed in carbon nanotubes (Frank et al. 1998), and other novel electronic properties are manifested by quantum dots (Timp 1999). Recently, electronic property aspects of materials, driven primarily by their vital importance to information technology, have dominated the scientific

interest and industrial application of nanotechnology. Many other novel combinations of properties can be expected to emerge for a wide range of materials as the nanoworld is explored.

Mechanical Properties

The grain size and grain boundary in polycrystalline materials or the concentration of strain fields significantly affects the mechanical properties as the dimensions approach the nanometer scale (Sternitzke 1997; Olemskoi, Valiev, and Khomenko 1999; Kumar, Van Swygenhoven, and Suresh 2003; Moussaif and Groeninckx 2003; Fratzl et al. 2004; Hierold 2004; Kothapalli et al. 2004). For example, grain size dependence is observed for properties related to plastic deformation along with decreased effective strain rate sensitivity (Jia, Ramesh, and Ma 2003). Modes of failure change as the scale of materials and structures shrink toward the nanoscale because of different mechanical and nonmechanical properties, such as the enhanced role of diffusion, which can modify fracture characteristics. Changes in the strength of nanoscale structural elements, the nature of friction, and other tribological properties will require new design strategies in the nanoscale regime (Adams et al. 2001).

Electronic/Optical/Magnetic Properties

Research on the electronic, optical, and magnetic properties of semiconductors at the nanoscale is growing at an astonishing pace. The fundamental properties of nanoscale semiconductor structures can be dramatically altered by controlling the size and shape of the structures without any change in their composition (Shipway, Katz, and Willner 2000; Qin et al. 2002; Wallace and Innis 2002; Wang 2002; Bonnell 2003; Bence 2004; Florey and Escobas 2004; Hao, Schatz, and Hupp 2004). When the electrons and holes in semiconductors are confined to dimensions less than their de Broglie wavelength (typically 1–30 nm), quantum mechanical size effects appear (Henglein 1995; Sun and Riggs 1999; Hao, Schatz, and Hupp 2004). Some of the observed effects of size are oscillatory behavior of the superconducting transition temperature with change in one atomic layer thickness (Guo et al. 2004), and resistivity enhancement and positive magnetoresistance with the diameter of nano wire (Liu and Chien 1998). The effect of shape on optical and electronic properties has also been recently observed (Xia et al. 2003; Hao, Schatz, and Hupp 2004). This gives impetus to future investigations of the effects of shape on other properties.

Thermal Properties

Thermal transport properties of nanostructured materials have received relatively little attention in the past decade (Che, Cagin, and Goddard 2000; Liu et al. 2002; Utracki and Kamal 2002; Adushkin, Andreev, and Popel 2004; Kikura et al. 2004; Liu and Kirchheim 2004). Several investigators have reported that nanoscale could result in significantly reduced thermal conductivities in nanostructured materials such as yttria-stabilized zirconia (YSZ), which could lead to improvements for applications such as thermal barrier coatings (Raghavan et al. 1998; Matsumoto and Matsubara 2004; Wang et al. 2004a). Reduced thermal conductivities are observed because of a reduction in the phonon mean free path that results from grain boundary scattering (Eastman et al. 1999). In contrast to the reduced thermal conductivity expected for nanostructured thin films or coatings, the thermal transport rates increase for fluids containing suspended nanoparticles. These nanofluids have recently been shown to exhibit substantially increased thermal conductivities and heat transfer rates compared to fluids that do not contain suspended particles (Patel et al. 2003; Eastman et al. 2004; Wen and Ding 2004).

Table 1. Classification of nanomaterials

Dimension	Nanomaterials
1 dimension <100 nm	Films, coatings, multilayers, nanopores
2 dimensions <100 nm	Tubes, fibers, wires, rods
3 dimensions <100 nm	Particles, hollow spheres, core-shells

CLASSIFICATION

All conventional materials such as metals, semiconductors, glass, ceramic, or polymers can, in principle, be synthesized in nanoscale dimensions. The spectrum of nanomaterials ranges from soft particles like microemulsions and liposomes to hard particles; they can be inorganic or organic, and crystalline or amorphous. Table 1 lists the nanomaterials classified according to shape.

Nanoparticles

Nanoparticles comprise several hundreds of atoms or molecules and can have a variety of sizes and morphologies (Kittel 1998; Pataki, Oszko, and Dekany 2003; Aslan et al. 2004). Some kinds of nanoparticles are already available commercially as dry powders or liquid dispersions in either primary size or aggregated states. With further processing steps, nanostructured powders and dispersions can be used to fabricate coatings, components, or devices. Industrial-scale production of some nanoparticulate materials like carbon black and titanium dioxide for polymer composites has been established for decades.

Some of the commercially important nanoparticles are silica (SiO_2), titania (TiO_2), alumina (Al_2O_3), iron oxide (Fe_3O_4), and microemulsions. Recently, nanoparticles of compound semiconductors (e.g., CdTe, GaAs, CdSe), metals (especially precious metals such as silver and gold), and alloys are finding increasing application (Pal et al. 2001).

Linear Nanostructures

Linear nanostructures include nanowires, nanotubes, and nanorods, which can be generated from different material classes (e.g., metals, semiconductors, and polymers) by various production techniques (Lieber 1998; Camerel et al. 2002; Xia et al. 2003). Carbon nanotubes are one of the most promising linear nanostructures, and they can be produced in different forms (e.g., single or multiwalled, filled, or surface modified). Carbon nanotubes are finding significant applications in nanoelectronics (data storage, flat-panel displays) and batteries, and as fillers for polymer nanocomposites.

Nanolayers

Nanolayers such as films, coatings, and multilayers are one of the most important aspects of nanotechnology, as they are extensively used in the microelectronic industry. The current Information Technology Age is the result of reproducible fabrication of these nanolayers. Nanoscale engineering of surfaces and layers produces a vast range of functionalities and new physical effects (e.g., magnetoelectronic or optical) (Chakravarti and Vetter 1998; Campbell 2001). Furthermore, nanoscale design of surfaces and layers is often necessary to optimize the interfaces between different materials (e.g., compound semiconductors on silicon wafers) to lower the lattice mismatch strain and to obtain the desired special properties. Materials with defined pore size in the nanometer range are of special interest for a broad range of industrial applications because of their outstanding properties with regard to thermal insulation and controllable material separation and release, and their applicability as templates for chemistry (Polarz and Smarsly 2002).

PRODUCTION TECHNIQUES

The two main routes of entry into the nanoworld are ultra-miniaturization resulting in smaller and smaller devices (working from the top down) and molecular manufacturing involving the manipulation of individual atoms or molecules (building from the bottom up). The former approach involves reducing the size of bulk material using mechanical, chemical, or other forms of energy. The latter approach deals with synthesizing nanomaterials from atomic or molecular species via self-assembly or chemical reactions, allowing the precursor particles to increase in size. Both production techniques can be employed in gas, liquid, or solid media, or in a vacuum.

Top-Down Approaches

The top-down methods of fabricating nanoparticles from bulk materials include high-energy ball milling, mechanochemical processing, etching, electroexplosion, sonication, sputtering, and laser ablation. Immediately after processing, nanoparticles are reactive owing to high surface energy, which is lowered by either agglomeration or adsorption of foreign species. If a reactive species is present, some additional reactions may occur. Nanoparticles can be coated during synthesis with a material that would prevent further interaction with other particles or the environment.

High-energy mechanical milling is widely used and is a very effective process for synthesizing metal-ceramic composite powders, because it allows incorporation of the metal and the ceramic phases in the same particle (Balaz et al. 2004). To produce nanoparticles of a specific material, a suitable precursor is chosen. Often a particular nanoparticle can be produced from a range of precursors, allowing the process to be optimized for industry. Oxides, carbonates, sulfates, chlorides, fluorides, hydroxides, and other compounds are all candidates for the precursor material. The chosen precursor is then milled with appropriate reactants.

Mechanical attrition, which produces a large amount of material, often contaminates the material. These industrial processes are mostly restricted to relatively hard, brittle materials, which deform, fracture, and cold-weld during the milling operation (Edelstein and Cammarata 1996). Typical objectives of the milling process include particle-size reduction (comminution), blending, solid-state alloying, and particle shape changes. The technique also produces a variety of nonequilibrium structures that include amorphous, quasicrystalline, and nanocrystalline materials. The mechanical attrition of multicomponent powder mixtures generally results in the formation of solid solutions extended in composition far beyond their equilibrium solubility limit (Shang, Bououdina, and Guo 2003). The potential of mechanical attrition to synthesize new materials under nonequilibrium conditions makes it a potential nanoparticle processing choice. For all nanocrystalline materials prepared, surface and interface contamination is a major concern. In particular, contamination by the milling tools and atmosphere can be a problem.

Bottom-Up Approaches

The methods to produce nanoparticles or nanoengineered surfaces from atoms and molecules are mainly sol-gel processing, chemical vapor deposition, plasma or flame spray synthesis, laser pyrolysis, atomic or molecular condensation, and self-assembly. Sol-gel processing differs from other chemical processes because of the relatively low processing temperature, making it cost-effective and versatile. In spraying processes, the reactants (gas or liquid as aerosols or mixtures of both) are introduced to a high-energy flame produced, for example, by plasma spray. The reactants decompose and particles are formed in a flame by homogeneous nucleation and growth. Rapid cooling results in formation of nanoparticles, and the cooling rate controls the crystallization.

Chemical Synthesis

Chemical synthesis permits the manipulation of matter at the atomic or molecular level. Chemical techniques are very versatile in that they can be adapted to nearly all materials (ceramics, semiconductors, and metals) and can be used for large-scale production. Most chemical routes rely on the availability of appropriate metal-organic molecules as precursors. Among the various precursors of metal oxides, metal β -diketonates, metal carboxylates, and metal alkoxides are versatile and available for most metals (Edelstein and Cammarata 1996). The challenges for chemical processing are finding the proper chemical reactions and processing conditions for each material. In the chemical synthesis of nanoparticles with desired properties, structural (crystalline or amorphous structure, size, shape, morphology, porosity) and chemical properties (composition of the bulk, interface, and surface) are important factors. Chemical homogeneity can be achieved because of mixing at the molecular level. To benefit from the advantages of chemical processing, an understanding of the principles of material chemistry, thermodynamics, and reaction kinetics is required. Formation and growth of the nanoparticles can be controlled by arrested precipitation and physical restriction. The former technique depends either on exhaustion of one of the reactants or on the introduction of a chemical that would block the reaction. The latter technique relies on physical restriction of the volume available for the growth of the individual nanoparticles using templates (Jain and Lakshmikumar 2002).

There are also potential difficulties in chemical processing. In some cases, the chemistry is complex and can be hazardous. Entrapment of impurities in the final product must be avoided or minimized to obtain desired properties. Scaling up for economical production of a large quantity of material may not be feasible for all systems. Another problem is that undesirable agglomeration at any stage of the synthesis process can change the properties of the desired nanoparticles.

With the advent of advanced thin-film processing methods like electron beam lithography, it has become possible to produce multilayered materials with precise control of the composition and thickness of the layers. In contrast to conventional bulk laminate composites, the individual layer thickness in multilayered thin films can be reduced to atomic or molecular dimensions by techniques such as dip-pen lithography (Ginger, Zhang, and Mirkin 2004).

Synthesis Using Organized Membrane

Using self-assembled membranes is an alternative approach to synthesizing stabilized, size-controlled nanoscale particles (Inglesten et al. 2001; Capek 2004). For example, Kumar et al. (1993) synthesized superconducting nanoparticles using water-in-oil microemulsion. Other examples of particles produced using this method include CdSe, silica, and silver. The self-organized organic and biological membrane assemblies include micelles, microemulsions, liposomes, and vesicles. The molecules of these assemblies have a polar head group with a nonpolar hydrocarbon tail, which self-assembles into membrane structures in an aqueous or nonaqueous environment. Aqueous and reverse micelles have diameters in the range of 3 to 6 nm and microemulsions in the range of 10 to 100 nm. Liposomes and vesicles are closed bilayer aggregates formed from phospholipids and surfactants, respectively. The membrane structures serve as reaction chambers controlling nucleation, growth, size, and shape of the particle. They also act as agglomeration barriers.

The main challenge for the top-down approach is the creation of increasingly small structures economically with sufficient reproducibility; whereas for the bottom-up approach the challenge is to make structures large enough and of sufficient quality economically. Current nanotechnology generally uses a combination

of both top-down and bottom-up approaches to produce a desired product.

Stabilization of Nanoparticles

The industrial-scale production and utilization of nanoparticles necessitates the ability to control particle size, shape, composition, particle-size distribution, and degree of agglomeration. But owing to their high surface area, and hence reactivity, nanoparticles tend to agglomerate, leading to loss of their unique properties. Commercial success or failure of nanoparticles in a particular application usually depends on the ability to prepare stable dispersions in fluids with controllable rheology. Therefore, it is often necessary to stabilize the nanoparticles with additional treatments. The common method to stabilize or modify the reactivity of the nanoparticles is encapsulation with a molecular or polymeric layer (Sun and Riggs 1999; Adler et al. 2000). A thin barrier shell enables compatibility of the particles with a wide variety of fluids. In this way, the nanoparticles retain their original chemical and physical properties, and the coating can be tailored for a wide variety of applications and environments ranging from extremely nonpolar (hydrophobic) to very polar systems. Coating nanoparticles with another material of nanoscale thickness can also alter the surface properties of nanoparticles. These core-shell structured nanoparticles display unique optical, mechanical, and magnetic properties (Caruso 2001). For example, Santra et al. (2004) recently developed nanoparticle composites for bioimaging.

CHARACTERIZATION

The wide range of potential applications makes nanotechnology truly multidisciplinary. Materials scientists, mechanical and electronic engineers, and medical researchers team up with biologists, physicists, and chemists to share their expertise on the nanoscale interactions in living and nonliving systems. One essential prerequisite for the development, manufacturing, and commercialization of nanomaterials is the availability of techniques for characterizing their physical, chemical, and biological properties. Powerful analytical detection and characterization methods also form the basis of risk assessment of nanomaterials in different environments such as water, soil, and air, and how they interact with the ecosystem.

The considerable wealth of detection and characterization methods for nanomaterials includes using AFM, STM, high-resolution transmission electron microscope, x-ray diffraction (XRD), and nanoindentation. These methods are used in research laboratories to study nanomaterial properties; however, most of them are not suitable for adoption into industry for on-line measurement because of their requirement for ultrahigh vacuum, sample preparation, and prolonged analysis.

INDUSTRIAL APPLICATIONS

Some nanomaterials had found a place in industrial markets before the current emphasis on nanotechnology. Now industries are more willing to incorporate nanomaterials into their processes to attract more customers, as long as they are economical. The major nanoparticles used are silica, titania, alumina, iron oxide, carbon black, nanoclay, and microemulsions. Research on nanotechnology in recent years has led to a significant increase in everyday applications. Some of the examples are

- Ever-increasing availability of new and high-performance electronic gadgets (e.g., flat-panel-display resolution enhancement by using nanocrystalline phosphors [Nanomats, undated])
- Antireflective, ultrathin polymer coatings with embedded nanoparticles used in sunglasses for durability and scratch resistance

- Clothes with stain-repellence and wrinkle-free, windproof, and waterproof properties. Clothes with additional electronic functionalities to monitor body conditions, facilitate drug release, and provide Internet access, etc., are anticipated.
- High-performance ski wax, which produces a hard and fast-gliding surface
- Tennis rackets with carbon nanotubes with increased torsion and flex resistance. The rackets are more rigid than current carbon rackets and pack more power (Nanocor 2004). Long-lasting tennis balls are made by coating the inner core with polymer-clay nanocomposites. These tennis balls have twice the lifetime of conventional balls.
- Sunscreens based on mineral nanoparticles such as titanium dioxide. Titanium dioxide nanoparticles have comparable UV protection as the bulk material, in combination with cosmetically desirable transparency.
- Nanoparticles in automotive parts and paints. The virtue of using nanocomposites for automotive applications is that less filler material is required to give better performance characteristics when compared to conventional materials (Kellar, Herpfer, and Moudgil 2003).
- In the area of health care, benefits from targeted and improved drug delivery systems. Nanoparticles are also used in developing new materials for bi implants and as sensors for bioimaging early detection of disease.

But all that has been achieved pales in the face of far greater opportunities that still need to be explored. Table 2 outlines the broad application of nanotechnology in various fields, and Table 3 lists some of the commercialized nanoparticles and their applications.

Table 2. Applications of nanotechnology in various fields

Industry	Application
Automotive	Lightweight construction, paints, catalysis, tires (fillers), coatings for windscreen and car bodies, etc.
Electronics	Data memory, displays, laser diodes, optical switches, conductive and antistatic coatings, etc.
Medicine	Drug delivery systems, bioimaging contrast medium, bioimplants, antimicrobial agents, coatings, etc.
Other	Flame retardants, construction materials, surface-processed textiles, "smart" clothes, food and drink packaging materials, wear protection of tools and machines (scratch-resistant coatings), ski wax, antifogging of glasses and goggles, antifouling coatings on ships, reinforced tennis rackets and balls, self-cleaning surfaces, sunscreen lotion

Table 3. Commercialized nanoparticles

Nanomaterial	Applications
Alumina	Ceramics, polishing slurries, coatings, catalysis
Carbon black	Fillers, pigments, inks, paper, building products
Carbon nanotubes	Electronic devices, structural elements, drug delivery
Fullerene	Paints, lubricants, coatings, electronic devices, nanocomposites
Iron oxide	Cosmetics, paints, pigments, ferrofluids
Nanoclays	Nanocomposites, packaging, construction materials
Silica	Catalyst support, "soft" silica-paints, foundry facings, polishing slurries, filtration media
Titania	Photocatalyst, paints, paper, self-cleaning surfaces
Zirconia	Catalysis, fuel cells, bioimplants
Zinc oxide	Cosmetics, catalyst, coatings, textiles

TRENDS AND OPPORTUNITIES

Modeling and Simulation

The emergence of unique phenomena at nanoscale creates a great need for theoretical and modeling efforts to understand the phenomena. Interactions between nanoscale structures and their surroundings can lead to many complex, collective properties. Theory and simulation tools are needed that can help predict these complex properties to design and produce better nanostructures for the future (Tsuchiya and Miyoshi 1999; Rafii-Taber 2000).

Inspiration from Nature

Living organisms are composed of structures that are indeed a part of the nanoworld. Proteins, enzymes, and DNA are in the nanometer range. The functioning of biological structures strongly depends on the nanoarchitecture of various components involved. Significant insight into nanoscale phenomena can be gained from nature's perfect biological systems. The limitations in everyday applications can be overcome by implementing acquired knowledge through human-made nanostructures. In addition, biological and artificial nanosystems can be coupled for application in both living and nonliving systems. Forming proteins with hierarchical complexity is an exquisite example of synthesizing nanomaterials through self-assembly.

ENVIRONMENTAL AND HEALTH CONSIDERATIONS

Nanotechnology promises huge benefits in wide areas of application ranging from superior lightweight materials, electronics, and biomedical applications to consumer goods. With the proliferation of nanotechnology as with any new technology, it is imperative to consider the other side of the coin—unintended impacts on human health and the environment. Studies on biological and environmental effects of nanotechnology lag far behind its exploration and implementation. Nanoparticles are on the same length scale as proteins and other bioactive molecules. The possibility of nanoparticles evading the natural defense system in bio- and ecosystems is a major concern. When considering the ill effects of nanoparticles, one should be aware that humans have been exposed to nanoparticles from natural sources like volcanoes, fires, and weathering of minerals, and to pollutant nanoparticles from power plants, incinerators, and vehicle emissions.

Environment

Nanoparticles can be released into the immediate environment in various ways such as from products in which they are not immobilized, by slow degradation of nanoparticles containing products, or by some mechanical action that releases nanoparticles. Nanoparticles can introduce new toxins or pose different unforeseen environmental hazards. Most of the research on nanoparticles produced by emission has focused on air pollution and its effect on ozone layer depletion. Currently, the focus of research is on the toxic aspects of nanoparticles. Nanoparticles can enter the biosystem via different environmental routes and travel up the food chain. Nanoparticles can be released to the environment by different means, such as industrial wastes, which can be taken up by organisms present in soil and water. Depending on their state of dispersion and surface activity, nanoparticles either can be toxic to the organism or can be accumulated in tissues, bones, or cells of organisms. Accumulated nanoparticles can then move up in the food chain to higher organisms. Recent studies show that carbon nanotubes can be toxic in a different way than common micrometer-scale fibers (Oberdorster et al. 2004; Warheit et al. 2004). In a separate study, when juvenile largemouth bass were exposed to 0.5 ppm of uncoated fullerenes

for 48 hours (Oberdorster 2004), the fullerenes accumulated in lipids of cell membranes and caused oxidative damage. Experiments also showed translocation of fullerenes to the brain. Further studies are required to determine the extent of damage, dependence on the fullerene modification process, and the dose. Persistence, accumulation, and toxicity are important factors determining the extent of damage to the environment posed by the nanoparticles (The Royal Academy of Engineering and The Royal Society 2004). Ease of recovery of nanoparticles from the environment in order to reduce their concentration to below acceptance levels is another important issue. Disposal of nanoparticles, in their primary size, to the environment should be treated as hazardous until further environmental and health risk data are available (Royal Academy of Engineering and the Royal Society 2004).

Health

With the advancement of nanotechnology, large-scale production and commercial use of nanoparticles are inevitable. For nanoparticles to have harmful effects on human health, they would have to come in contact with cells and cause adverse reactions. Nanoparticles released into the environment can enter the human body via three major routes—inhale, ingest, and dermal penetration. All three routes are commonly exposed to micrometer-sized particles and microorganisms. The human body has its own defense mechanism for protection against microorganisms, which act in a similar way for micrometer-sized particles (Alberts et al. 2002). Depending on the route, nanoparticles can evade the body's defense system and enter the living tissues.

Inhalation

Thousands of particles enter the airway during inhalation. The air pipe, or trachea, is lined with hair-like structures called cilia that restrict the passage of particles into the lungs. The epithelial, or surface, cells of the trachea are covered with mucous and macrophages. If the particles or microorganisms reach the epithelial cells, they are engulfed by macrophages and carried to lymph nodes, where they are discarded. If particles are present in a sufficiently high dose, they can cause inflammation and scarring of lung tissue, as in pneumonia or silicosis (Gehr and Heyder 2000). High proportions of inhaled nanoparticles are deposited in tracheobronchial and alveolar regions of the lung (Oberdorster 2001; Oberdorster et al. 2004). Nanoparticles, because of their small size, can enter the cell directly through the cell membrane. They are also known to diffuse into the lungs through epithelial cell lining. Inhaled nanoparticles can translocate to the liver, brain, and other organs through blood vessels and the central nervous system (Oberdorster 2001; Oberdorster et al. 2004).

Dermal Exposure

The skin acts as a protective barrier against microorganisms. The outermost layer of skin, called the epidermis, is composed of cells that keep replenishing every few weeks. Below the epidermis lies the dermis, which consists of living cells, nerve endings, sweat glands, and blood vessels. Macrophages are present in abundance in the dermis and provide a defense against entry of particles and microorganisms. Excessive exposure to particles or microorganisms can produce inflammatory reactions, and prolonged inflammation can also result in skin damage and diseases. Particles and microorganisms, though restricted by the epidermis, can reach the dermis if the epidermis is damaged by cuts or wounds. But the small size of nanoparticles helps them penetrate the epidermis and enter the bloodstream. Aerosolized beryllium nanoparticles were shown to penetrate epidermis (Tinkle et al. 2003). Agglomeration of airborne

nanoparticles can reduce the risk of dermal penetration. Titanium dioxide, zinc oxide, and iron oxide nanoparticles are commercially used in cosmetics (sunscreens and lipsticks), and current dermal exposure is limited to these nanoparticles (Royal Academy 2004).

Ingestion

Ingested particles first encounter a low-pH environment in the stomach. Acidic juices secreted by the stomach's cells help digest food, dissolve toxins, and inactivate microorganisms. The food broken down by the stomach enters the intestine, where it is absorbed. The epithelium of the intestine is impermeable to many large molecules and particles but absorbs small molecules. The epithelium also secretes mucus and digestive fluids that can dissolve particles and toxins and degrade microorganisms. Recently, it has been shown that intestinal epithelial cells can absorb nanoparticles of drugs (Pamujula et al. 2004; Russell-Jones 2004). Although the tests were performed for oral drug delivery, possibility of entry and accumulation of other nanoparticles through the gastrointestinal tract cannot be neglected.

Nanoparticle exposure to industrial workers depends on production techniques, storage, and disposal systems. Nanoparticles stored in a liquid medium or in an agglomerated state are less prone to dermal penetration. The toxic effect of nanoparticles depends not only on its surface area but also on dosage, clearance mechanism, surface chemistry, and state of dispersion. Combined interdisciplinary and international efforts are reevaluating the risks posed by nanotechnology to make it safe and beneficial.

NANOCLAYS

Introduction

Clays have played an immense role in the development of humankind from the earliest use for building shelters and pottery dating back to the Neolithic stage of civilization. The reason lies in their plasticity and abundance. Clays are typically hydrous aluminosilicates with a particle size of usually less than 4 μm . The layer structure of clays imparts moldability in a wet state and rigidity in a dry state.

Clay nanoparticles or nanoclays have come into focus in the last decade because of their ability to enhance mechanical, thermal, and optical properties of polymers in which they are used as fillers. Nanoclay-filled polymers have a weight advantage because the filler does not significantly change the density of a nanocomposite and the nanosize of clay maintains the optical transparency. Polymer-clay nanocomposites have found extensive applications in packaging and in the automobile and aerospace industries. Since enhanced mechanical and thermal properties can be achieved at a lower cost using a smaller quantity of nanoclay, many polymer industries incorporate nanoclays to improve their products.

Structure

Clay minerals are part of the larger class of silicate minerals called phyllosilicates. The layer structure of clays is composed of silica tetrahedral and alumina octahedral sheets. The silica tetrahedral sheet consists of individual SiO_4 tetrahedrons that share three of four oxygen atoms. The tetrahedrons are linked to form a hexagonal network with a composition of Si_4O_{10} . The apical oxygen atoms are shared with the octahedral sheet. The alumina octahedral sheet consists of individual octahedrons that share oxygen or hydroxyl edges. These octahedrons are also linked in a hexagonal network. The tetrahedral and octahedral sheets are stacked in different ratios, as summarized in Table 4. Depending on the ratio of tetrahedral and octahedral sheets, the layer thickness varies from 0.7 nm for 1:1 phyllosilicates to 2 nm for 2:1 phyllosilicates. Weak van der Waals forces hold the layers together to form stacks. The gap between the layers is called the interlayer or the gallery. The interlayer distance

Table 4. Classification of clay minerals

Structure	Group	Minerals
1:1	Kaolin-Serpentine	Kaolinite, halloysite, dickite, nacrite, chrysotile, antigorite, lizardite
2:1	Talc-Pyrophyllite	Talc, pyrophyllite
	True mica	Phlogopite, biotite, muscovite, phengite, celadonite
	Brittle micas	Margarite, clintonite, anandite
	Chlorites	Clinochlore, chamosite, donbassite, sudoite, cookeite
	Illite	Illite, glauconite
	Smectite	Montmorillonite, beidellite, saponite, nontronite, hectorite
	Vermiculite	Vermiculite

is 0.95 nm in the absence of any counterions or water of hydration (Otterstedt and Brandreth 1998). The clay layer can have substitutional defects like Al^{3+} substituting Si^{4+} and Mg^{2+} or Fe^{3+} substituting Al^{3+} . The net negative charge acquired by clay layers from substitution is counterbalanced by the presence of cations like Ca^{2+} and Na^+ in the interlayer spacing.

The most commonly used layered silicates for nanocomposite applications are montmorillonite, hectorite, and saponite, which belong to the 2:1 phyllosilicates family (Ahmadi, Huang, and Li 2004). The 2:1 phyllosilicates have two silica tetrahedral layers sandwiching one alumina octahedral layer, as shown in Figure 1.

Polymer-Clay Nanocomposites

Toyota Central Research and Development Laboratories first synthesized the polymer-clay nanocomposite with polyamide 6 and montmorillonite cation exchanged with 12-aminolauric acid (Usuki et al. 1993a; 1993b). The polyamide 6-clay nanocomposites have enhanced mechanical and thermal properties compared to conventional clay composites. Since then, various other thermoplastic and thermosetting polymers such as epoxies (Xu, Bao, and He 2002), cellulose acetate (Park et al. 2004), polyester (Chang and Kim 2004), polyvinyl chloride (Gong et al. 2004), polystyrene (Wang et al. 2004c), polyimide (Yu et al. 2004), polypropylene (Ding et al. 2005), and polyurethane (Solarski et al. 2005) have been used for synthesizing nanocomposites with significantly improved properties.

Intercalation and Exfoliation

In polymer-clay nanocomposites, the clay should be dispersed in nanosize range to achieve the superior properties. The state of dispersion is often characterized using XRD and transmission electron microscopy (TEM) (Eckel et al. 2004; Wang 2004b; Wei, Tang, and Huang 2004) and recently using techniques such as small-angle neutron scattering (Malwitz et al. 2004), AFM (Park et al. 2004) and laser-induced fluorescence spectroscopy with optical probes (Maupin et al. 2004).

Intercalation and exfoliation are the two major steps involved in clay particle dispersion in polymers, as shown in Figure 2. The polar nature of clay sheets is not always compatible with polymers, which are usually hydrophobic. Modifications via cation-exchange reactions with various organics, including cationic surfactants (alkyl ammonium/phosphonium), are commonly used to render the hydrophilic clay layers partially hydrophobic. Cationic surfactants adsorb between the clay layers with their hydrophilic heads oriented toward the clay sheet and hydrophobic chains acting as spacers between the clay layers. Thus, the organically modified clays have larger interlayer spacing, which helps in intercalation or exfoliation during further processing with polymers.

Figure 1. Layer structure of 2:1 phyllosilicate

Figure 2. Clay dispersion in polymer nanocomposites

In intercalation, the polymer chains or molecules diffuse into the interlayer, increasing the spacing. The layer–layer interaction still exists through weak van der Waals forces. The clay layers remain parallel to each other; this can also be characterized by XRD, which shows increase in d-spacing. Dilution of clay or peak broadening, however, could be misinterpreted for exfoliation (Eckel et al. 2004).

Exfoliation separates the clay layers and randomly disperses them in a polymer matrix. The interlayer spacing is very large and there is no layer–layer interaction with van der Waals attraction forces. Since the clay layers are randomly dispersed, XRD cannot provide any information on the extent of dispersion because of any absence of peaks; hence, TEM is used. Initial interlayer spacing of cation-exchanged clay is required for exfoliation. For exfoliation of clay, Eckel et al. (2004) calculated the theoretical mean linear intercept distance between clay layers to be about 50 to 80 nm, in agreement with the experimental measurements. Exfoliation has been experimentally and theoretically shown to be strongly dependent on

the shear rate and viscosity of the matrix during processing, the Hamaker constant, interlayer spacing, layer–polymer interactions, and organic modifier–polymer interactions (Cho and Kamal 2004; Fornes, Hunter, and Paul 2004).

Production Techniques

Polymer-clay nanocomposite production techniques can be grouped into three categories: in-situ polymerization, solution polymerization, and melt intercalation.

In-situ Polymerization

The first polymer-clay nanocomposite developed by Usuki was synthesized by in-situ polymerization (Usuki et al. 1993a; 1993b). In this technique, the organically modified clay is added to a polar monomer solution. The monomer diffuses into the high surface energy interlayer of clay. Polymerization initiator is added after the monomer–interlayer equilibrium is reached. The monomers present

in the interlayer polymerize, shifting the equilibrium. More monomers are driven into the interlayer, further increasing the interlayer spacing, and in some cases resulting in exfoliation (Ahmadi, Huang, and Li 2004). Since clay can act as a catalyst, the presence of impurities can change the polymerization reaction. This method is commonly used for thermosetting polymer nanocomposites such as epoxy organo-clay nanocomposite.

Solution Polymerization

In solution polymerization, the organically modified clay and polymer are added in a polar or organic solvent. Hence the first requirement is that polymer should be soluble in the solvent. The polymer diffuses into the interlayer, resulting in intercalation. The solvent is subsequently evaporated, leaving behind intercalated nanocomposite. The nature and polarity of the solvent are critical factors in determining the intercalation process. The major drawbacks of this technique are the large amount of solvent needed and the solvent compatibility with organically modified clay as well as polymer.

Melt Intercalation

In melt intercalation, polymer is mechanically mixed with organically modified clay at a temperature above the softening or melting point of the polymer. The polymer diffuses into the interlayer, resulting in intercalation. Although this method is applicable to only thermoplastic polymers, it has the advantage of using conventional polymer-processing equipment. Because this method also does not need any solvent, there is no need for postsynthesis recovery.

Properties

Polymer-clay nanocomposites are superior to conventional clay-filled or pristine polymers because of enhanced thermal endurance, flame resistance, tensile strength and modulus, biodegradability, reduced shrinkage, and pristine polymer optical properties.

Thermal Properties

The thermal properties of polymer-clay nanocomposites are studied by thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). Blumstein first reported the high thermal endurance of polymer-clay nanocomposite in 1965 (Blumstein 1965). Using nanoclay, the heat distortion temperature and crystallization temperature of the polymer composite can be increased by 20°C (Ke 2003; Gong et al. 2004). Increased thermal decomposition temperature by 30°C is also reported (Chiu et al. 2004; Solarski et al. 2005).

Flame resistance of polymer-clay nanocomposites is studied by cone calorimetry and radioactive gasification experiments. The heat release rate and flammability have been shown to be 30% to 35% lower for polymer-clay nanocomposites compared to conventional polymer-clay composites (Song and Yao 2004; Wang 2004c).

Mechanical Properties

Conventional clays are being used as filler in polymer mainly to improve, marginally, its mechanical properties. Nanoclays, on the other hand, can increase the tensile strength and modulus by 100% to 400% (Chang and Kim 2004; Chen 2004; Wei, Tang, and Huang 2004). Since the filler content is usually less than 5% for nanoclays, the processing is easier and the products are lighter.

Chemical Properties

Polymer-clay nanocomposites reduce gas and liquid permeabilities, including reduced solvent uptake. Nanoclays can decrease the gas permeability coefficient by 35% (Chen 2004). The increased resistance is attributed to tortuosity and higher modulus of clay nanopar-

ticles (Ahmadi, Huang, and Li 2004). Osman et al. (2004) showed that intercalation can decrease the permeability coefficient by 20%, whereas exfoliation increased the permeability coefficient by 10%. Polymer nanocomposites can also be used in anticorrosion applications (Yu et al. 2004).

Optical Properties

The optical properties of polymer-clay nanocomposites are studied using UV-visible transmission spectroscopy. Although nanoclay is known to scatter light in the ultraviolet region, nanoclays with dimensions of less than one quarter of visible light wavelength are optically transparent (Ahmadi, Huang, and Li 2004; Yeh et al. 2004). Thus polymer-clay nanocomposites have optical properties similar to pristine polymer.

Improvement in the previously mentioned properties, combined with ease of processing and low volume of clay needed, promises widespread application of polymer-clay nanocomposites.

Pigments

George Podolsky and Austin H. Reid Jr.

The pigments industry represents one of the most demanding and technology-intensive applications of industrial minerals. Pigments are used in all major materials known to man. The building products, polymers, glass, paper, and paint and coating industries are major users of inorganic mineral pigments. Various clay minerals and titania are more widely used as white pigments than, for example, silica, alumina, calcium carbonate, and zinc oxide. Similarly, iron oxides and chromates are representative of the important colored pigments. In this chapter, discussion focuses primarily on natural and synthetic iron oxides typifying the colored pigments, and on titanium dioxide exemplifying the white pigments, as these find the predominate use in the industry. To familiarize the reader with the various terminologies and definitions specific to the pigments industry, these two important pigments are discussed in a single chapter.

IRON OXIDE

Iron oxides are unique in that they are the only significant colored mineral found in a natural state suitable for use as a pigment after being pulverized to pigmentary size (typically, less than 1 μm). The global production of iron oxide pigments in 2000 was estimated to be 1.5 Mt (Will 2004). In addition to their abundance (about 7% of the earth's crust), iron oxides have the advantage of low cost, permanency, and nontoxicity. The amazing durability of iron oxides is reflected in the numerous examples of beautiful prehistoric art found in cave paintings in many regions of the world. Through the centuries, succeeding civilizations have used iron oxides as a major source for decoration and protection when these properties were desired. In the last century, the chemical industry improved on nature by developing a complete range of synthetic iron oxide pigments that surpass the pigments produced from natural iron ores in uniformity, color quality, and chemical purity. Globally, the combined annual production of natural and synthetic iron oxide pigments is valued at approximately \$2 billion (Will 2004).

Terms and Definitions

As with other pigmentary minerals, it is necessary to make a distinction between the natural or mineral pigments and the synthetic pigments. Natural pigments are products derived from selected ores and should not be confused with iron ores mined for steel production. Iron ores that are mined for steel must be capable of being mined and reduced to iron on a competitive commercial basis. These ores are selected on the basis of iron content and processing

economics. It is therefore unusual when iron ores for steel production are suitable for use as mineral pigments. Natural pigment ore sources are selected for their special physicochemical properties and are able to command a premium price over the iron ores used for steel manufacturing.

Synthetic pigments, and in this instance iron oxides, are pigments produced from basic chemicals. Chemical synthesis produces pigmentary particles directly, as opposed to the use of comminution, the procedure common to preparing all natural iron oxide pigments.

Classification

An important characteristic of a pigment is its color. Therefore, a logical separation can be made on this basis.

- Yellow iron oxide pigments
 - Natural mineral origin
 - Goethite
 - Lepidocrocite
 - Ochres
 - Siennas
 - Limonite
 - Synthetic pigments
 - Goethite (αFeOOH)
 - Lepidocrocite (γFeOOH)
 - Akagenite (βFeOOH)
- Red iron oxide pigments
 - Natural mineral origin
 - Hematite
 - Siderite (calcined)
 - Pyrites (calcined)
 - Synthetic pigments
 - Hematite ($\alpha\text{Fe}_2\text{O}_3$)
- Brown iron oxide pigments
 - Natural mineral origin
 - Umbers
 - Limonite (calcined)
 - Siderite (calcined)
 - Goethite (bog ore or sulfur mud)

- Synthetic pigments
 - Blends of hematite, goethite, and magnetite
 - Coprecipitated hematite–magnetite
 - Maghemite (γ -Fe₂O₃)
- Black iron oxide pigments
 - Natural mineral pigments
 - Magnetite
 - Slate (mixed minerals)
 - Synthetic pigments
 - Magnetite (Fe₃O₄)

Pigmentary minerals, natural or synthetic, have important physicochemical properties that distinguish them from metallurgical, cementitious, construction, agricultural, and other types of industrial minerals.

The iron oxide content of natural minerals is critically important. Also important are the amount, the type, and the form of any companion minerals. For example, an iron ore possessing good pigmentary qualities but associated with appreciable quantities of quartz would be undesirable because of the difficulty in grinding quartz and the regulatory issues surrounding crystalline quartz. High percentages of organic matter in the ore would require calcination to decompose the organics, and then grinding. Synthetic oxides, on the other hand, exhibit a high iron content because of chemical synthesis. They also contain minimal impurities, the degree to which depends on the synthetic route.

Chemical Properties

Most of the pigmentary iron ores are relatively nonreactive (Mellor 1953; Casey 1966) and contain only traces of heavy metals and toxic elements; these are usually chemically bound in the form of complex silicates. Synthetic pigments produced from basic raw materials have the advantage that purification steps can reduce the heavy metal content (e.g., lead, antimony, arsenic, cadmium, mercury, selenium) of the starting raw materials. If subsequent precautions are followed to avoid processing contamination, the heavy metal impurities in synthetic oxides can be about one tenth that of the best naturals.

Iron oxide pigments have a high degree of lightfastness. This term refers to the ability of a pigmented film to resist color changes and other physicochemical degradation caused by exposure to radiant energy.

Physical Properties

The physical properties of iron oxide pigments are usually more important than the chemical properties in view of their inertness. Several physical properties require definition to provide a clear understanding of the merit of a pigment and to distinguish between naturals and synthetics or pigments of other families.

Oil Absorption. Oil absorption is that weight of vehicle required to wet a definite weight of pigment to form a paste. Numerous methods (Stewart 1942; Von Fisher 1948; Anon. 1972b, 1983) and devices can determine oil absorption. The values in this chapter are from standards of the American Society for Testing and Materials (ASTM) spatula rub-up procedure. Oil absorption, or binder demand, is an important property because it relates to particle size, shape, and surface characteristics and places certain limitations on paint formulation or other end uses where solid–liquid interactions are important.

Surface Area. Two pigments of essentially the same mean particle size may have quite different surface areas. This may be due to shape or surface characteristics such as porosity, pore size distribution, smoothness, and convolutions. Because spectral and

surface energy properties depend on the particle surface, surface area becomes an important factor. The surface area of a material is the area of the total external surfaces, including pores but excluding *internal* (isolated) pores. When external pores are smaller than the molecule of the media being absorbed, they are not measured. The most widely accepted and fundamental method for calculating surface area is by measuring the adsorption of a gas, usually nitrogen (Brunauer et al. 1938; Herdan 1953) and is designated as the BET method. The value obtained expresses specific surface area in square meters per gram.

Particle Size. No single method or instrument can adequately measure particle sizes in the range from 100 to 0.01 μ m. Significant improvements have been and continue to be made, however, in the range and accuracy of the wide variety of instrumentation available. For example, laser diffraction-based instrumentation is available for ranges of 0.02 μ m to more than 2,000 μ m. A key is to completely disperse the particles and minimize the measurement time. Otherwise, various stages of reagglomeration of the primary particles will be measured. Complete books have been devoted to this subject, which is probably the most important physical property of pigments. It is not sufficient to state an average particle size since the size distribution of particles is equally important. Generally, electron microscopy is still used to most accurately measure the primary particle size of iron oxides. Terms that are often confused in particle technology are as follows:

- *Primary particle:* Sometimes may be referred to as *discrete particle*; a single unit of matter that can change in size only by the breakdown or fracture of chemical bonds within its structure.
- *Crystallite:* A minute single crystalline unit, i.e., that part of a particle that has its atoms and molecules arranged in a perfect crystal lattice. A discrete particle comprises an assemblage of many crystallites.
- *Aggregate:* A group of discrete particles bound together by strong chemical bonds.
- *Agglomerate:* A group of discrete particles or aggregates bound together by weak physical bonds.
- *Flocculate:* Groups of aggregates or particles usually formed in suspensions and readily dispersed with minimal forces.

Shape. In some applications, particle shape can have a more profound effect than size. Micaceous iron oxide (lamellar platelets) and acicular particles contribute completely different characteristics to a pigmented system than their equivalent spherical counterpart. Various techniques have been devised to apply numerical values for shape factors (Herdan 1953; Cadle 1955). Pigments are classified into five categories according to shape: (1) spheroidal, (2) cubical, (3) nodular, (4) acicular, and (5) lamellar.

Optical Properties. The optical properties of pigments depend on the molecular and crystal structure and are influenced by the size and shape of the primary particles. Because pigments are rarely used in their powder state, the ultimate effect depends on the entire system. Light entering a pigmented system may be absorbed, reflected, or refracted through particle-to-particle interactions. The manner and intensity of the light reflected results in spectral reflectance, which can be measured with a spectrophotometer.

Magnetic Properties. Iron oxides are usually antiferromagnetic (Schieber 1967), but they can also be ferromagnetic when produced synthetically as well as in certain natural mineral species. The magnetic properties of ferromagnetic materials can be determined by various techniques; a few of the more common are magnetic moment balance, vibrating sample magnetometer (VSM), and B–H (magnetic flux–magnetic field) meter.

Figure 1. Hysteresis loop used to characterize magnetic iron oxides

Magnetic materials are best described by measuring the response to a magnetic field of varying intensity. This produces a magnetization, or BH curve, as shown in Figure 1. Ferromagnetic materials may then be characterized with values of coercivity (H_c), remanence (B_r), and saturation (B_m) at a specified field strength in Oersteds (H).

Natural Iron Oxide

Natural iron oxide minerals mined for pigment applications normally require more than simple grinding to attain commercial status. The major minerals are discussed along with their chemical and physical properties. The chemical compositions, especially those of goethite and hematite, do not represent the pure mineral but rather the range as received by the pigment manufacturer.

Hematite

This important iron-bearing mineral, besides providing a source for steel manufacture, is a major source for mineral pigments. Table 1 gives the physicochemical properties of hematite.

Major iron ore sources are sedimentary, as exemplified by the Lake Superior deposits in the United States. Hematite also occurs as igneous, volcanic, hydrothermal, metamorphic, and weathered deposits. Several deposits are unique for their high color value, such as those on the Island of Ormuz in the Persian Gulf or Spanish deposits near Malaga. Micaceous hematite, unique for its lamellar structure, is mined in Austria and Australia. Synthetic processes for the manufacture of micaceous iron oxide have been developed.

Goethite

The second most common iron-bearing mineral is goethite. This includes other hydrated mineral iron oxides such as the limonites, ochres, and siennas. Table 2 gives the physicochemical properties of goethite.

Goethite is typically formed under oxidizing conditions as a weathering product of ferrous minerals, siderite, pyrite, and magnetite, and is widespread as deposits in bogs. It is commonly associated with hematite, pyrolusite, manganite, calcite, quartz, lepidocrocite, clay minerals, and limonite. Hydrated iron oxide is also called limonite. By x-ray examination, most limonites are actually cryptocrystalline goethite with absorbed or capillary water (Palache, Berman, and Frondel 1944). Several excellent pigment ore sources are found in India. Domestic ochre is mined in Georgia and Virginia.

Lepidocrocite

This natural mineral has essentially the same chemical composition as goethite but different crystallographic constants. Table 3 gives the physicochemical properties of lepidocrocite.

Table 1. Physicochemical properties of hematite

Chemical formula	Fe_2O_3
Chemical composition of ore	50% to 95% Fe_2O_3 , associated with other iron or silicate minerals
Crystal class	Hexagonal; scalenohedral
Habit	Thick to thin tabular, as rosettes, rhombohedral, sometimes platy; also earthy
Physical	No cleavage, fracture subconchoidal to uneven, hardness of 5–6
Reaction mechanism	Will form, by solid-state reactions, a wide variety of ferrites of the composition $M \cdot \text{Fe}_2\text{O}_4$ where M represents one or more metals such as manganese, zinc, magnesium, nickel, barium, strontium, and yttrium. These ferrites have important electrical and magnetic properties and to a lesser extent pigmentary properties. Zinc ferrite (tan), magnesium ferrite (brown), and manganese ferrite (black), however, are important pigments in applications requiring heat stability.
Other properties	
Melting point	1,475°C–1,565°C
Boiling point	Decomposes
Solubility	Insoluble in water and common organic solvents
Index of refraction	3.042
Specific gravity	5.26
Magnetic	Usually antiferromagnetic, exists as ferromagnetic synthetically and naturally

Table 2. Physicochemical properties of goethite

Chemical formula	$\alpha\text{FeOOH} \cdot x\text{H}_2\text{O}$
Chemical composition of ore	50% to 88% Fe_2O_3 , 9% to 10% H_2O , balance silicate or clay minerals
Crystal class	Orthorhombic; dipyrnidal
Habit	Prismatic and striated; also in tablets or scales, grading into acicular and long prismatic forms; also earthy
Physical	Cleavage [010] perfect, [100] less so, fracture uneven, hardness of 5.0–5.5
Reaction mechanisms	Will form ferrites through solid-state reactions as noted under hematite. Can also be converted from $\alpha\text{FeOOH} \cdot x\text{H}_2\text{O}$ to $\alpha\text{Fe}_2\text{O}_3$ by heat and to ferromagnetic $\gamma\text{Fe}_2\text{O}_3$ by reduction and oxidation.
Other properties	
Melting point	Decomposes; naturals (finely ground) start to dehydroxylate at 190°C and is essentially dehydroxylated at 320°C; synthetics start at 180°C and are completely dehydroxylated at 300°C.
Boiling point	Decomposes
Solubility	Considered insoluble in water and common organic solvents, 0.0015 gpl cold water
Index of refraction	2.26–2.27
Specific gravity	3.3–4.0
Magnetic	Antiferromagnetic

Lepidocrocite is formed under similar circumstances as goethite and is often associated with it.

Magnetite

The mineral magnetite occurs abundantly and is found worldwide in many locations. The magnetic nature of this mineral gives it considerable historical interest going back to antiquity. Table 4 lists its physicochemical properties.

Magnetite deposits are found as magmatic segregation deposits, as an accessory mineral in igneous rocks, in metamorphic

Table 3. Physicochemical properties of lepidocrocite

Chemical formula	$\gamma\text{FeOOH}\cdot x\text{H}_2\text{O}$
Chemical composition	50% to 89% Fe_2O_3 , 10% to 11% H_2O ; minor amounts of silicates
Crystal class	Orthorhombic; dipyramidal
Habit	As flattened elongated scales sometimes striated; usually as isolated crystals or plumose groups on a matrix
Physical	Cleavage [010] perfect, [100] less perfect, [001] good; hardness of 5.0
Reaction mechanisms	Lepidocrocite converts to ferromagnetic $\gamma\text{Fe}_2\text{O}_3$ on heating at low temperature and to $\alpha\text{Fe}_2\text{O}_3$ at high temperature; will enter into other reactions similar to goethite
Other properties	
Melting point	Decomposes, similar to goethite
Boiling point	Decomposes
Solubility	Considered insoluble in water and common organic solvents
Index of refraction	1.94
Specific gravity	4.05–4.10
Magnetic	Antiferromagnetic

Table 4. Physicochemical properties of magnetite

Chemical formula	Fe_3O_4 (also $\text{FeO}\cdot\text{Fe}_2\text{O}_3$)
Chemical composition	84% to 99% Fe_3O_4 associated with minor amounts of silicate minerals; purity can be high for a natural mineral
Crystal class	Isometric (cubic); hexoctahedral
Habit	Usually octahedral; well-formed, nearly perfect crystals are common; occurs in coarse to fine-grained masses
Physical	Octahedral parting on [111] especially good; conchoidal to uneven fracture; [001], [011], [138] also reported as parting planes in magnetite; hardness of 5.5–6.5
Reaction mechanisms	Synthetic magnetites start to decompose in air to $\gamma\text{Fe}_2\text{O}_3$ at 105°C and are completely oxidized at 385°C. Natural magnetite, if finely ground, will start to decompose at 124°C and be completely oxidized at 550°C. It will form spinel compounds of the general formula $M\cdot\text{Fe}_2\text{O}_4$, where <i>M</i> represents metals such as manganese, zinc, and barium.
Other properties	
Melting point	Decomposes
Boiling point	Decomposes
Solubility	Insoluble in water and common organic solvents
Index of refraction	2.42
Specific gravity	5.16–5.17
Magnetic	Ferromagnetic

deposits in limestones, in chlorite schists with pyrite, in sulfide vein deposits, and in meteorites. Commercial deposits are found in the United States, Norway, and Sweden.

Pyrites and Siderites

These minerals do not fall into the class of iron oxides because they require transformation by heat to convert to the oxide. As such, they are potential raw materials rather than end products.

Manufacturing

The manufacturing procedures for the naturals must be designed around the starting ore base. For example, siderite (FeCO_3) requires

Figure 2. Particle-size distribution comparing a fine particle synthetic with a natural iron oxide

calcination to convert to the oxide, whereas pyrites cinder (calcined pyrite), although essentially Fe_2O_3 , must be freed of its acidic residues. Also, certain ores, although suitable for use by simple grinding, develop more desirable colors if calcined. Other natural ores, siennas, and umbers are produced in raw and calcined form.

Some of the hematites and the magnetites are magnetically beneficiated to increase the chemical purity and remove undesirable siliceous minerals. This is particularly true if the end use has chemical purity requirements such as do ferrites (Anon. 1965). Magnetic beneficiation is most efficient if the mesh size is controlled within fairly narrow limits. Therefore, wet magnetic beneficiation usually follows the crushing and screening operation and precedes fine grinding or calcination. The critical variables are magnetic field strength, pole and plate design, solids concentration and feed rate, demagnetizing field strength, and wash-water feed rate. The process produces a superconcentrate with purities of greater than 99.5% Fe_2O_3 or Fe_3O_4 from lower-grade concentrates.

Fluid energy mills, micronizers, and improved methods of classification have enabled manufacturers to produce natural iron oxide pigments for many applications where chemical purity and the ultimate discrete particle size are not factors.

Products

The broad selection of manufacturing procedures, coupled with the wide variety of natural ore, results in about 100 different products being marketed in the United States alone. Selling price and end-use considerations result in a range of products being produced from a single ore body. For example, a natural iron oxide for a paint primer must be finely ground but has wide latitude in its color specifications. Concrete coloring pigments, however, have stringent color requirements but moderate fineness requirements.

All natural products, without exception, are subjected to some type of final grinding. Comminution, as opposed to particle synthesis, produces characteristic fragmented particles covering a wide size distribution. Figure 2 compares a synthetic iron oxide with a natural ground iron ore, showing a major difference in size and fragmented nature of the natural ore.

Generally, natural iron oxide pigments have weaker tinting strengths because of the larger particle size and lower color purity.

Uses

Many of the applications for natural iron oxides are based on low cost and permanency (Anon. 1991a). There is some overlap in use

of the naturals and synthetics; both, for example, are used extensively in paint and coatings.

Paint and Coatings. The variety and types of industrial coatings are too numerous to mention individually. There are several general types of paints in which natural iron oxides provide excellent properties and represent major uses. *Primers* vary in the degree of pigment loading and function as a base for various topcoats. The primer pigments are usually hematites and can be highly loaded because of high density, fairly large particle size, and low oil absorption.

Industrial maintenance finishes for railway equipment and metal structures largely employ hematites. Micaceous iron oxide (Anon. 1972b), because of its platelike structure, has found extensive use in Europe in railway maintenance coatings, bridge paints, industrial maintenance finishes, and other exterior applications.

Micaceous iron oxide is not a primer or a rust-inhibiting pigment but is used as part of a corrosion control system. To capitalize on its platelike structure, the paint formulator must grind the paint properly to secure a lamellar film structure (Anon. 1971a).

Natural umbers and siennas have unique color characteristics that are not easily matched with synthetics and hence they are the major pigments in stains. With the increased use of prestained wall panels, this is an important application.

The naturals are also used in general interior and exterior house paints, but to a lesser extent than synthetics.

Electronic. Natural iron oxides are used to some extent in preparing barium ferrite ($\text{BaFe}_{12}\text{O}_{19}$) and to a lesser extent in preparing manganese zinc ferrite ($\text{Mn}_x\text{Zn}_y\text{Fe}_2\text{O}_4$). The magnetic properties of manganese zinc ferrites are very sensitive to impurities, and hence the use of naturals has been limited. Highly beneficiated magnetite or hematite can be used to prepare barium ferrites. Beneficiated magnetite when finely ground is used in magnetic inks (Love 1961). The magnetic energy (remanence) of an ink is proportional to the volume of iron oxide in the ink. Because of the low binder demand of the dense natural magnetites, high loadings of 60% to 70% by weight of magnetite pigment can be obtained.

Rubber, Plastics, and Related Compounds. Natural pigments are used to a limited extent in rubber and many of the more common plastics such as vinyls, phenolics, polyurethanes, and epoxies (Woernle 1967). Umbers contain a high percentage of manganese, which can cause undesirable effects such as accelerating the aging of rubber and retarding the curing of polyesters. Generally, these markets favor using the synthetic pigments because of their improved purity, dispersibility, and color value. The cost advantage of natural pigments, however, remains a key factor in their continued use.

Concrete Products and Building Materials. Natural oxides are suitable for coloring concrete, mortar, concrete roof tile, concrete pavers, and similar building materials. In coloring concrete, the tint is the important characteristic and synthetic pigments have replaced most of the naturals because of their higher tinting strength. In some cases, blends of synthetic and natural pigments may be used for a cost advantage.

Rouge. Before the introduction of the float glass process, large tonnages of natural iron oxides were used in polishing plate (flat) glass. This use has declined dramatically because of the float glass process. Ophthalmic rouge and metal-polishing rouge represent a small market. Specially processed grit-free hematites having high glass removal rates are required. Another market is in coloring glass and is referred to as a *batch rouge*.

Miscellaneous. Natural iron oxides are used in numerous other industrial applications such as foundry-core washes, ceramics, paper, and fertilizer, and as the iron source in glassmaking.

Synthetic Iron Oxides

The four major types of synthetic iron oxides are reds, yellows, browns, and blacks. All can be prepared from basic chemicals, usually iron salts and alkalis. The advantage of chemical synthesis is that it gives precise control over three important pigment parameters: particle size, particle shape, and chemical purity.

Raw Materials

Iron Salts. Only two iron salts of commercial significance—ferrous sulfate and ferrous chloride—are used to manufacture synthetic iron oxides. Ferrous sulfate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$), or *copperas*, as it is commonly called, was the historical base for red oxides produced by calcination. Subsequently, ferrous sulfate was used as the iron salt to produce yellows, reds, browns, and blacks by precipitation. The increased use of hydrochloric acid to pickle steel resulted in an abundance of by-product ferrous chloride.

Ferrous sulfate for pigment production is available from three sources. The first consists of neutralizing scrap iron with H_2SO_4 . A second is by-product sulfate pickle liquor from steel mills. This is a mixture of about 15% FeSO_4 (ferrous sulfate) and 10% H_2SO_4 , the balance being water. The excess acid is converted to FeSO_4 by neutralization with iron. The third major source is the titanium pigment industry, which produces by-product $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$. This iron salt must be redissolved and purified. The subsequent processing is the same as steel mill pickle liquor.

Domestic pigment manufacturers rarely use ferrous chloride to produce color pigments. Its use limitations are more fully discussed in the following section on by-products.

Iron. The iron source is generally stampings and punchings of light gauge, soft black steel. Pigment producers avoid scrap that is plated (galvanized) or contains alloying elements because of the adverse effect of these impurities.

Alkalis. The major alkali used in the United States is sodium hydroxide (NaOH) followed by ammonium hydroxide (NH_4OH). Environmental regulations, however, have significantly reduced the use of ammonium hydroxide. Lime (CaO) is used to a limited extent but could become more important with increased regulation of the use of ammonium hydroxide. Both sodium hydroxide and liquid ammonia (NH_3) with a high degree of chemical purity can be purchased, which is less true of commercial limes. Sodium carbonate is sometimes used as well.

By-products. Most of the by-products require further processing either as raw materials or as end products. Spray roasting ferrous chloride pickle liquor produces Fe_2O_3 and HCl . The spray-roasted oxides can be returned to the steelmaking process but usually are landfilled. Some steelmakers, however, divert a portion of the Fe_2O_3 to other applications where color is not important. The spray-roasted oxides are generally poor in color quality but can exhibit good chemical purity. Even poorer in quality are the dust collector-recovered oxides produced from the basic oxygen steelmaking process. The thousands of tons of these two waste products have depressed pigment prices in markets where color quality is not a major consideration.

Mill scale, although abundant, has found only very minor usage in the iron oxide industry. One of the major contaminants of this product is refractory material from spalling of furnaces and linings. Also, mill scale is not a completely oxidized product and cannot be used for pigmentary purposes without further processing.

Other waste products that have attracted attention over the years but have not proven suitable for commercial pigments are red mud from bauxite processing, sponge iron from cement copper mining operations, and sulfur mud or *yellow boy*, a precipitate

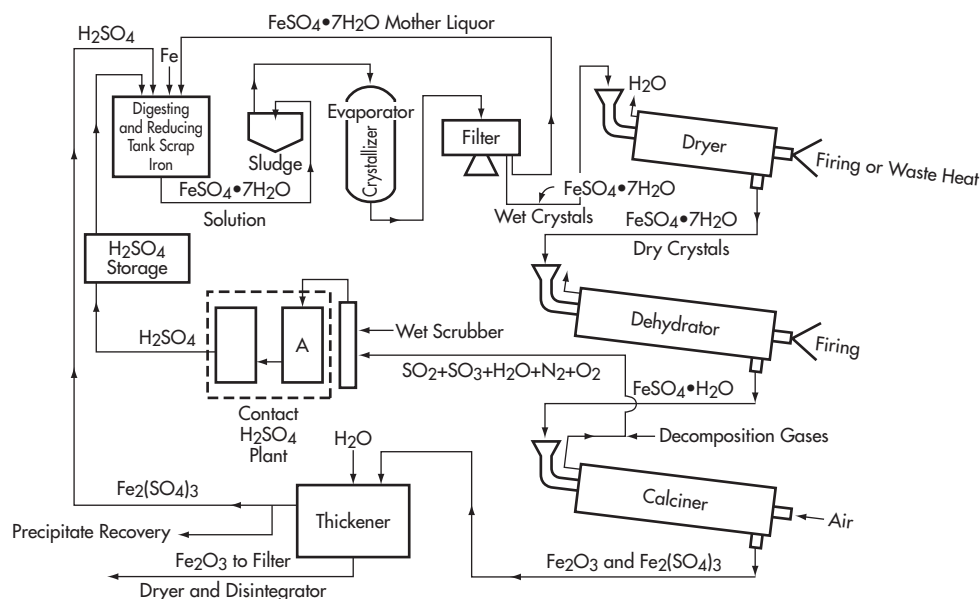

Figure 3. Simplified flow diagram for synthetic iron oxide (copperas red type)

formed from acid coal mine waters. Failure was generally caused by unacceptable color purity.

Manufacturing Processes

The three major methods for manufacturing synthetic iron oxides are thermal decomposition of iron salts or iron compounds, precipitation of iron salts usually accompanied by oxidation, and organic reduction processes using iron. The last route has become less significant as new processes have replaced iron as the reductant.

Thermal Decomposition of Iron Salts. There are numerous combinations of processing techniques, depending on the starting basis. Only one flow sheet (Figure 3) is outlined, starting with scrap iron and sulfuric acid (Ayers 1946). If the starting base is steel mill pickle liquor or titanium copperas, the process is essentially the same with the exception that steps may be introduced to remove undesirable impurities.

Figure 3 illustrates the production of iron oxides by the calcination of ferrous sulfate. These products are commonly known as copperas reds. One major advantage of this thermal decomposition process is that the products of combustion are reclaimed and reused.

One of the earliest synthetic iron oxides and a variation of the calcination of ferrous sulfate is the Venetian reds. These oxides were produced by calcining an intimate mixture of ferrous sulfate and lime or preferably hydrated lime ($\text{Ca}(\text{OH})_2$). The calcination product must be ground to be suitable for pigmentary applications. The process has one advantage in that the kiln product does not require washing. Venetian reds have been supplanted by other synthetic reds.

Most steel mills have converted from sulfuric acid to hydrochloric acid in their pickling lines. This facilitates the recovery of the acid and generates iron oxide as a by-product. The amount of by-product iron oxide generated exceeds the total present production of iron oxide pigments. The by-product oxide may be pelletized and recycled into the steel process. Some of the oxide is also used as a raw material for the ferrite industry.

Precipitation Reactions. Precipitation processes were developed in the early 1900s (Penniman and Zoph 1921) but did not

achieve commercial importance until the 1930s to 1940s. Since that time, the major growth in synthetic iron oxide manufacture has been by precipitation technology. The precipitation process produces yellows, reds, browns, and blacks. Additional products can be produced by subsequent procedures such as calcination and reduction, among others.

In the manufacture of yellow oxides by the Penniman–Zoph process (often referred to as the scrap iron process), the initial reaction is one of nucleation, wherein the reaction of an iron salt and an alkali forms a seed nucleus. The nucleation reaction is normally conducted in an excess of FeSO_4 and can be described by the following equations:

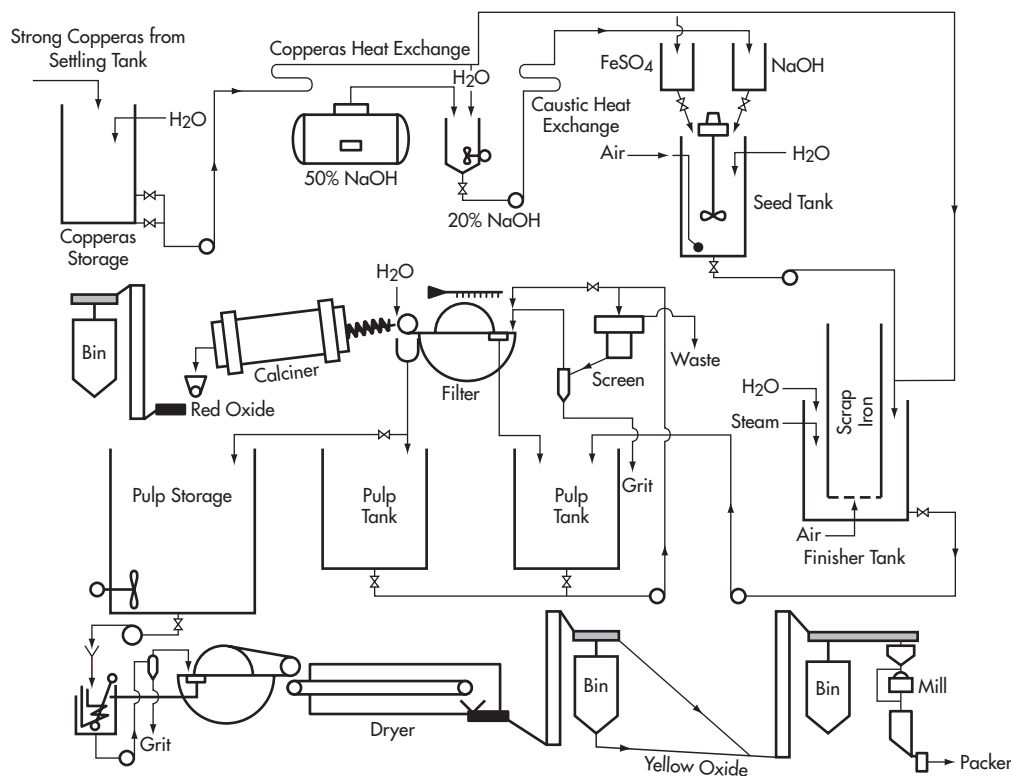

The nucleus is transferred to a precipitator containing FeSO_4 , H_2O , and iron, usually in the form of thin-gage stampings. The seed particles are continuously circulated over the bed of iron in an oxidizing environment at elevated temperatures (60°C to 88°C), and, as the iron oxidizes or dissolves, the reaction products precipitate on the nuclei, causing the particles to grow. The chemical reactions involved are

also

From the simplified chemical reactions, the precipitation process would not appear to be complex, but the actual gas–liquid–solid chemical interactions are still not completely understood. A host of variables affect the reaction and the products. Some of the more

agent. Most organic chemical manufacturers, however, use different reducing agents or, if they use iron, are more concerned with the organic compound than with the iron oxides produced. Consequently, most iron oxide sludges from the reduction of organic compounds are, generally, an impure waste product.

If nitrobenzene is reduced to aniline in the presence of various chemicals, it will produce specific colors of iron oxides (Love 1946). AlCl_3 (aluminum chloride) can be used to produce yellow oxides but is omitted when blacks are desired. Reds can be produced by calcining either yellows or blacks. In each, the choice of iron source is carefully controlled and usually consists of iron filing or iron powder. This route is known as the Laux process.

Miscellaneous Manufacturing Processes. Another related product line consists of tan pigments. The tan pigments are zinc or magnesium ferrites (Downs and Martin 1950, 1959). These are formed by interaction of iron oxides with metallic oxides to form the ferrites. The reactions are as follows:

A final example of a product that is between a synthetic and a natural, with respect to its variable nature and very high impurity level, is the by-product oxide from the basic oxygen furnace (BOF) steel production. The by-product oxide is collected from gases evolved during the lancing process.

Products and Properties

The synthetic manufacturing approach opens up an almost infinite number of distinct product possibilities. An iron oxide producer wishing to cover all major synthetic marketing applications may have more than 100 iron oxide products available for sale. The product shape often becomes critical to optimum pigment performance.

The typical shape of a calcined copperas red (Figure 5) can be compared to a precipitated red oxide (Figure 6).

Figure 7 shows a yellow iron oxide before (left) and after (right) being subjected to a high temperature of 1,038°C.

Figure 8 shows a synthetic, precipitated black iron oxide.

Specifications

Specifications vary widely based on the end-use application. A paint manufacturer will be most concerned with color and top size, whereas a manufacturer of ferrites requires chemical purity (see Table 5).

Natural pigments will have much wider tolerances and, in some cases, are usually not as tightly controlled for color and tinting strength.

Applications

As previously noted, there is an overlap between natural and synthetic oxides. Some applications, either by custom or necessity, use only synthetics.

Paint. Synthetic oxides have higher chroma or color purity and greater tinting strength than natural oxides. The color purity variation from lot to lot can be closely controlled, which is not always true of a natural. They have excellent dispersion properties. Consequently, they are ideally suited for universal tinting systems, powder coatings, automotive finishes, appliance enamels, and interior and exterior paints (Parker 1965; Patterson 1967; Anon. 1968; Parfitt 1969). They are nontoxic and meet existing federal regulations.

Figure 5. Light synthetic red iron oxide, copperas red type

Figure 6. Light synthetic red iron oxide, precipitated type

A group of ultrafine iron oxide pigments are known as transparent or low-opacity products. These pigments have found application in the automotive industry in the manufacture of metallized finishes in the copper and orange color range. These iron oxide pigments are used with other metal pigments (e.g., aluminum) to produce striking automobile finishes.

Electronic Applications (Ferrites). The conventional synthetic reds had the major share of the ferrite raw material market until about 1975. Today, steel mill oxides derived from ferrous chloride (regenerated, or "regen," oxides) have become dominant in this market. The soft ferrite market remains a more limited consumer of synthetic reds. Copperas reds and calcined yellows are sometimes preferred because of chemical purity, high density, and minimum volatiles (Stephens 1959). The 1990 western world production of permanent magnetism was estimated to be about \$2 billion; the iron oxide portion of the total ferrite dollar sales was less than 5% (Kline 1981).

Figure 7. Change in morphology in synthetic yellow iron oxide (FeOOH) by heat treatment to red oxide (Fe_2O_3)

Figure 8. Synthetic black iron oxide (precipitated magnetite)

Magnetic Recording. Magnetic tape recording and magnetic ink oxides represented a U.S. market of greater than 14 ktpy in 1990 for all applications, but this market continues to decline drastically. Most magnetic recording tape applications that use gamma ferric oxide or cobalt-treated gamma ferric oxide products are being replaced by optical recording discs (CDs and DVDs).

The requirements for audio, video, and data recording vary, and special oxides are produced for these applications. Slow recording speeds and high fidelity require ultrafine oxides. Cobalt modification is required to elevate the intrinsic coercivity of gamma ferric oxide to the higher levels required by video and the higher density applications.

Magnetic inks for check processing (magnetic image character recognition, or MICR), credit cards, and railway tickets use synthetic magnetite or other ferrites, which provide high pigment concentrations in the binder system.

Table 5. Typical color pigment specifications

Mass color	1.5 DE CIE-Lab, 3.0 FMC-II units (maximum)*
Tint tone	1.5 DE CIE-Lab, 3.0 FMC-II units (maximum)*
Tint strength	±5% of standard (maximum)
Fe_2O_3 (copperas red type)	Minimum 99.0%
Fe_2O_3 (precipitated red type)	Minimum 96.0%
+325 mesh sieve retention	0.10% maximum
Moisture at 110°C	0.30% maximum
H_2O soluble salts	0.20% maximum
Dispersion for specialty milled reds	6.0 minimum Hegman fineness (ASTM D1210)
Oil absorption	±10% of standard (maximum)

* International Commission on Illumination (CIE) $L^*a^*b^*$ color system; CIE-Lab color difference method as described by Nassau (1998). FMC-II described by Chickering (1971).

Concrete Products and Building Materials. Synthetics have the advantage of greater tinting strength and uniformity and have replaced naturals in most applications. This is a growing market, consuming approximately 50 % of the 1.5 Mt global total (Will 2004). Construction grades are produced in three forms: fine powder, liquid, and granular. Popularity of the granular form continues to grow. Granulation processes include compaction, spray drying, and extrusion.

Plastics, Floor Tile, Linoleum, and Rubber. High chemical purity, high chroma masstones, and strong tints result in a low cost per color unit, accounting for high usage of synthetics. Many plastics require stabilization, which is more easily accomplished with the consistent chemical purity of the synthetic iron oxide.

Chemical and Miscellaneous. Synthetic iron oxides are used singly or in combination with other elements as catalysts in various conversions for ammonia, styrene, butadiene, hydrogen, desulfurization, and formaldehyde (Mills 1964). Aerospace and airbag propellants also use iron oxides, although the azide technology requiring iron oxide oxidants has been essentially replaced by

alternate technologies using organic fuels and other oxidants. A critical rocket application is the Space Shuttle booster rockets. A copperas red-type iron oxide is used as a burn rate control agent in this application. Here, the iron oxide serves as a catalyst to promote the activity of the ammonium perchlorate oxidizer.

Iron oxide is added to animal feeds, primarily for color coding, and also as a coloring agent for pet foods.

Iron oxides are considered to have a "generally recognized as safe" (GRAS) rating by the Food and Drug Administration (FDA). Certain grades that meet the maximum of 3 ppm arsenic, 10 ppm lead, and 3 ppm mercury are approved for drug and cosmetic use. Iron oxides for pet foods must not exceed 5 ppm arsenic, 20 ppm lead, and 3 ppm mercury. The European Union has also adopted E-172 regulations. These require conformance for 9 trace metals: maxima in ppm are 5 arsenic; 50 barium; 5 cadmium; 100 chromium; 50 copper; 20 lead; 1 mercury; 200 nickel; and 100 zinc; also, 1.0% maximum water soluble salts. Even lower nickel levels are becoming the standard in Europe.

Synthetic oxides are used for ophthalmic polishing and as the iron source for coloring glass and providing ultraviolet (UV) absorptive properties.

An interesting application is in medicine. Magnetic oxides have the ability to absorb myxoviruses, which can then be magnetically separated from the system (Warren 1969). Another medical application for magnetic iron oxides is in analyzing red blood cell population and targeting cancer sites with magnetically modified medicines (N. Shaffer, personal communication).

Marketing

The demand for iron oxides is closely related to domestic and worldwide requirements of the construction, coatings, automotive, plastics, electronics, and chemicals industries.

Iron oxide prices were very stable from 1960 through 1970. The inflationary costs of labor and supplies plus high energy and environmental regulation costs necessitated significant price increases from 1970 to 1990. Today, with continued increases in energy costs and dramatic increases in scrap prices, price adjustments are required. The 11-year price trend of a selected range of natural and synthetic iron oxides is found in Table 6; they continue to be the most cost-effective color pigment. Pricing for special grades, including high-purity iron oxides and electronic grades, is not shown in the table.

Iron Oxide Statistics—United States

Table 7 shows U.S. sales, including import and export data, for natural and synthetic iron oxides for 1998–2002. The value has continued to decrease because of a steady price erosion. Table 8 shows U.S. sales data available to the U.S. Geological Survey (USGS) by iron oxide type.

Environmental Considerations

One of the major factors affecting iron oxide manufacturing today has been federal and state regulations regarding the environment. Whereas the major steel and titanium processors were disposing of their iron salts by dumping, they are now required to recover and process these salts before disposal. This has resulted in large quantities of cheap by-product iron oxides. The iron oxide manufacturers have also been required to recover and process any soluble iron salts that were previously discharged, resulting in increased manufacturing costs.

Table 9 shows the heavy metal content in several iron oxide products, both natural and synthetic. The synthetic iron oxides are generally low in these elements, as can be expected by the chemical

control provided in their manufacture. Certain grades of copperas reds show particularly low values of arsenic, lead, and mercury. Precipitated reds, synthetic yellows, and synthetic blacks are somewhat higher in the heavy metals but are low compared with the naturals. Table 9 shows this natural red to be particularly high in arsenic, lead, and barium. Natural iron oxides can show considerable variation in heavy metal content in different areas of the world and sometimes in the same ore deposit.

Trends and Opportunities for Iron Oxides

Two major markets for iron oxides are coatings and concrete products. Today, key new sources for iron oxides include China and India. It is estimated that in 2000, China produced 26% of the global total of 1.5 Mt; Western Europe, 25%; India (largest natural iron oxide producer), 22%; Japan, 15%; and the United States, 11% (Will 2004). The growth of China as the leading synthetic iron oxide producer is likely to continue.

New iron oxide developments during the past 20 years have included granular forms of iron oxides and new versions of nano-sized (less than 0.1 µm) materials. It is expected that future developments will focus on using iron oxides in nano composites and

new chemical applications, with the paint/coatings and construction industries continuing to dominate, as in the past.

TITANIUM DIOXIDE

White pigments have been known and used since antiquity. Metal oxides such as antimony oxide and lead oxide were in general use for centuries. Zinc sulfide, barium sulfate, and blends of these materials with each other and with other materials have been used since at least the late 1800s and are still used in some applications today. The advent of the 20th century saw the large-scale commercial introduction of titanium-based white pigments possessing many advantages over those used historically. High brightness, high opacifying power, lack of toxicity, and long-term stability allowed titania-based pigments to rapidly overtake other materials used in these applications (Wicks, Jones, and Pappas 1992). Engineering of new surface architectures was developed in the 1950s. The continued refinement of this aspect of manufacture has led to a tremendous increase in the

ability to tailor these ultimately composite materials into ever-broader end-use arenas (Braun, Baidins, and Marganski 1992).

Pigmentary materials based on the chemistry and physics of rutile and anatase titanium dioxide are the predominant items of commerce used to generate white, opaque articles and to tint materials. These pigmentary materials are almost never simply titanium dioxide. An intermediate titanium dioxide is generated from a titanium-bearing ore such as ilmenite or from a titanium slag. The surface architectures of these materials are then modified by both inorganic and organic chemistry to produce a variety of preferred performances based on intended market end use (Furlong 1994). In addition, the particle-size distribution and the solid-state phase chemistry have marked effects on the manner in which these materials interact with actinic radiation (van de Hulst 1981). Despite these facts, it is not uncommon for users to describe titanium dioxide pigments simply as *Pigment White 6*. This oversimplification can lead to erroneous grade selections and subsequent failure in use

of end products made with improperly selected pigments. Given the ubiquity of titania pigments in the commercial world, it is of value to understand those factors differentiating performance in various end uses and to understand their origins. This, in large part, forms the basis of this section on titanium dioxide.

Terms and Definitions

The pigmentary materials discussed here are referred to as *titania pigments* for sake of conciseness. Certain specific terms are often used in discussions of these materials and this short list covers those considered most important.

- **Anatase:** Anatase is a polymorph of TiO_2 with a refractive index of 2.5. Tetragonal, space group $I4_1/amd$ (141) (Wells 1975)
- **Brookite:** Brookite is a polymorph of TiO_2 . Not of commercial utility in pigmentary applications. Orthorhombic, space group P/cab (61) (Wells 1975)
- **Durability:** Although TiO_2 readily absorbs UV light in the solar spectrum, it also acts as a photocatalyst as a result of the formation of electron-hole pairs from its wide band gap and resulting semiconductor behavior. To prevent the UV-induced catalytic destruction of paints, polymer films, and other matrices in which it may be used as an opacifier and/or a UV screener, the surfaces of the particles are modified to prevent photochemical reactions (Rabek 1990; Diebold 2005).
- **Dispersability:** For a titania pigment to provide optimal performance, it must be uniformly dispersed and distributed in the carrier matrix of the finished good in which it is used. As TiO_2 itself has a relatively high surface-free energy, surface modifications are made to lower the surface-free energy and thus improve the compatibility of the pigment with the medium in to which it is being dispersed. This reduces the amount of energy required to carry out the initial dispersion, thus lowering costs for the end user. For fluid systems, surface modifications are also used to stabilize the dispersions once they have been formed. The intention is to both prevent flocculation and to reduce settling over time (Wicks, Jones, and Pappas 1994).
- **Particle-size distribution:** To maximize the scattering of visible light, the median particle size of pigmentary titanias is typically controlled to approximately $0.25 \mu\text{m}$, or roughly half the wavelength of blue light in the visible spectrum. Distributions are typically log-normal. Particles larger than $\sim 0.5 \mu\text{m}$ are avoided because of the adverse impact these have on certain appearance properties in film applications (particularly gloss) (Allen 1990).
- **Refractive index:** The refractive index is the ratio of the velocity of an electromagnetic wave (e.g., visible light) in a vacuum to the velocity of an electromagnetic wave in the medium of interest. Differences in refractive indices between carrier matrices, such as paint or polymer films, and a filler, such as a titania pigment dispersed in them, largely dictates opacity (Wicks, Jones, and Pappas 1992).
- **Rutile:** This is a polymorph of TiO_2 with the highest refractive index available (2.73). Tetragonal, space group $P4_2/mnm$ (Wells 1975)
- **Surface treatment:** This is an inorganic or organic modification to the surface of an intermediate TiO_2 particle. Surface treatments are used to induce specific surface architectures that dictate the end-use behavior of the material. Inorganic treatments are typically comprised of a hydrous, often multiphase coating of silica and alumina, often deposited step-

wise. The alumina coating may be further modified by the addition of other species. Other oxides, particularly zirconium oxide, may also be included. Organic treatments are typically added as the last tier of the surface architecture. These may include polyols, alkanolamines, siloxanes, silanes, fatty acids, and a number of other materials.

Production

Titania pigments are produced by two large-scale processes: the sulfate and the chloride routes. At present, roughly 75% of the titania pigments produced worldwide are manufactured using the chloride process, and the balance is produced by the sulfate process. Plants are currently in operation in North and South America, Europe, Asia, Africa, and Australia. Ores used as feedstocks for these processes are obtained from a wide variety of sources.

Infrastructure

The infrastructure supporting the titania pigments industry includes the mining industry (titaniferous feedstocks), the steel industry (slag ores), and the chemical industry (sulfuric acid, chlorine, and related raw material feedstocks).

Titanium is generally considered to be the 9th most abundant terrestrial element. Titanium-containing ores are mined on every continent except Antarctica. Both rock ores and sand ores (usually found in alluvial deposits) are mined commercially. Because of the high relative density of titanium-bearing ores, it is possible to find relatively uniform deposits of very high heavy-mineral content in a large number of locations. Slags containing high concentrations of titanium are generated in certain steelmaking processes. These materials may be ground to a useful size and consumed in both the chloride and the sulfate production processes. Higher concentrations of titanium in feedstocks obviously result in lower volumes of nontitanium side streams that must be managed as a part of the overall manufacturing process. As such, higher-grade feedstocks generally command considerably higher prices than low-grade materials.

Chlorine for the chloride process is generally obtained from chlor-alkali plants. Although the majority of the chlorine used is recycled in the process, some so-called make-up chlorine is required to maintain production. With the decrease in chlorine use in the bleaching of paper, the relative consumption of chlorine by the TiO_2 pigments industry has increased, most markedly in the United States. Sulfuric acid and oleum used in the sulfate process are generally produced by the oxidation of elemental sulfur and by the conversion of off-gases containing the oxides of sulfur. These are also largely recycled in the process, although dilution occurring during processing results in the requirement of concentration of dilute waste acid before reintroduction to the process.

Raw and Intermediate Materials

The critical raw materials for the sulfate process are titanium-bearing ores, strong sulfuric acid, and surface treatment chemicals. The chloride process requires titanium-bearing ores, chlorine, oxygen, and surface treatment chemicals. Single ores or their blends can be used in either process. The ore requirements for the two processes are not identical. Certain ores are not amenable to dissolution in strong sulfuric acid, and as such cannot be used as feedstocks for the sulfate process. Ores of extremely fine particle size cannot readily be used in either process because of material handling and related processing concerns. The nontitanium elemental composition of the ores is also quite important, because these materials report to a secondary stream from the primary pigment process. The difficulty in handling these streams is generally taken to be directly proportional to the nontitanium content of the feedstock.

Technology

The two major technologies in use today for the manufacture of titania pigments are based on the sulfate process, commercialized early in the 20th century, and the chloride process, commercialized in the 1950s.

Sulfate Process

In the sulfate process, titanium-containing ores are dried, crushed, and reacted with sulfuric acid to form a mixture of titanium sulfate and other sulfates, predominantly iron, in a batch process. Scrap iron is added to facilitate the precipitation of iron as copperas (iron sulfate heptahydrate). The remaining titanium-bearing solution is then purified. The precipitation of titanium dioxide from the solution is then induced, and the material formed serves as the intermediate from which the finished titania pigments are produced. The intrinsic polymorph obtained from the sulfate process is anatase. Calcination is required for conversion to rutile (Anon. 1991b).

Chloride Process

In the chloride process, a mixture of titanium-bearing ores, a carbon source, and chlorine gas are allowed to react at high temperature in a continuous process. The resulting mixture of chlorides is then separated and the resulting titanium tetrachloride is further purified. This material is then reacted with oxygen at high temperature to form an intermediate from which the finished titania pigments are produced (Braun, Baidins, and Marganski 1992).

Economic Production Factors

The production of titania pigments is quite capital intensive at any commercially reasonable scale. Although many extremely small (<10,000 tpy) sulfate-technology facilities exist around the world, more than 80% of the material produced globally is generated by facilities with individual capacities ranging from approximately 50,000 tpy to more than 350,000 tpy. It is also a concentrated industry in terms of the producers involved, with about 80% of world capacity operated by the top 5 producers.

The largest factor operative in the costs associated with the manufacture of titania pigments is feedstock costs—most specifically, the cost of titanium-containing raw materials. Although a large variety of ores are used in the industry, they can generally be separated into four classes: ilmenites, beneficiated ilmenites, slags, and natural rutiles. The cost spectrum spanned by these materials is quite large, often a factor of four to five, depending on requirements. Because everything in the ore except the titanium must be removed, higher-grade ores are intrinsically advantageous—but also, therefore, command higher prices. In addition, some titanium-bearing ores occur in association with naturally occurring radioactive materials, specifically minerals containing either thorium or uranium. These are generally not of great value to the industry because of government regulations in some countries and concerns about the formation of low-level radioactive materials that result from concentration effects in certain manufacturing processes.

Contaminants such as alkaline earth elements can also reduce the utility of some ores. In addition, some elements cannot be readily removed in the sulfate process, leading to the formation of unacceptable color centers in the final product. Most transition metals (particularly iron, chromium, vanadium, and nickel) can degrade the color performance of titania pigments to an extent that is commercially unacceptable at levels of less than 25 ppm. The oxidation state of the

contaminant can also have a substantial impact on the degree of color degradation. Transition metal contaminants must therefore be reduced to extremely low levels to avoid adverse color effects in finished pigments.

Consumption

Global consumption of titania pigments is about 6 Mtpy. Because of the ubiquity of titania pigments, consumption typically tracks gross domestic product (GDP) and has been noted to be a leading indicator of economic performance.

The materials are consumed in a very broad manifold of end uses. These can be broken out into the following categories: Coatings (paints), polymers, paper, and specialties. Coatings is the largest segment globally, followed in order by polymers, paper, and (distantly) by other specialty end uses. More than half of the titania pigments produced are consumed in the manufacture of coatings.

Specifications

Specifications for titania pigments differ for each end use. One measure, *hiding power*, applies across all end-use segments. It is a measure of the opacifying capability of a given pigment in a given application on a weight basis. Titania pigments are primarily sold as opacifying agents, and as such, their performance in this regard is most critical and applies across all end-use segments (Balfour 1990).

Coatings Applications

The most common applications in coatings follow.

- **Color:** This refers to what some call “dry color.” It is measured on a dry pigment sample and is typically reported in terms of the International Commission on Illumination (CIE) $L^*a^*b^*$ color system. Several other color systems are also used by various industries (Berns 2000). For titania pigments it is a direct measurement of transition metal (nontitanium) impurities remaining after the manufacturing process.
- **Dispersability:** A measure of the difficulty with which the pigment is incorporated into a matrix. Both distributive and dispersive mixing play a role in this behavior. Performance can be evaluated by standard methods including the preparation of a millbase or a finished paint, and subsequent evaluation using a Hegman gage or related device to determine the number of oversized particles present. Resistance to flocculation is also an important aspect for paint systems, as the end user does not wish the particles to form agglomerates once the dispersion has been prepared.
- **Durability:** Long-term durability performance is initially evaluated during product development using an actual exterior panel exposed for 24 to 48 months in a variety of locations around the world to obtain a broad representation of natural conditions. From these, derived accelerated tests have been generated. For surface-modified pigments using dielectric encapsulation as a means of inducing durability (a widely practiced route), it is possible to measure the amount of “exposed”—and, therefore, photoactive—titania by means of an acid solubility test. This test correlates very well with long-term durability testing and is sufficiently rapid to allow its use as a product release test (Holtzen, Diebold, and Niedenzu 2002).
- **Gloss:** This is an appearance characteristic related to the degree to which the pigment decreases the level of luster or brightness inherent in an unpigmented film because of changes in the relative ratios of specular and diffuse reflectance. It is typically evaluated in an actual paint system and is

carried out using standard gloss meter measurement technology. The particle-size distribution, which is related to this appearance characteristic, is also often measured (Wicks, Jones, and Pappas 1994).

- **Grit:** This is typically measured by screening an aqueous dispersion of the pigment through a 325 -mesh screen to determine the amount of large agglomerates in the pigment. High grit content adversely impacts appearance of finished paint films and also results in reduced throughput in the paint manufacturing process.
- **Oil absorption:** This property reflects both the surface area and the surface pore structure of the pigment. It is typically measured by determining the amount of an organic fluid (linseed oil, for example) that can be absorbed by a measured amount of the pigment. The formulation of a paint can be greatly affected by changes in oil absorption.
- **pH:** Reciprocal of hydrogen ion content, measured for an aqueous dispersion of the pigment. The chemistry of some paints can be very sensitive to pH and must be monitored closely (Hunter 1996).
- **Resistance:** This is electrical resistance, as measured on an aqueous dispersion of the material. It is a measure of the ionic content of the pigment. Excessive ionic content can adversely affect paint chemistry.
- **Tinting strength:** This is a means of determining the unit opacifying power of a pigment, usually carried out in a paint system and measured by standard optical techniques.

Polymers

The information on polymers is taken primarily from Saechtling (1992).

- **Dispersion:** For polymer applications, different types of dispersion measurements are used depending on the end use. For vinyl systems, it is common to use a rolled soft vinyl sheet to determine dispersion performance. It is also possible to use polyolefin dispersion measurements. The two most common tests are screen-pack dispersion and the so-called filter test. In both, the pigment sample is combined with a polymer (typically a polyethylene) at 50% to 70% pigment loading by weight. This is then extruded through a screen. The material on the screen may be analyzed for oversize particle content (screen pack value) or the increase in pressure in the system as a function of time may be measured (the filter value). In both cases, a 500-mesh screen is typically used, although extremely high-performance applications such as fibers may utilize 1,400-mesh screens (Shenoy 1999; Holtzen, Reid, and Sedar 2003).
- **Color, pH, and resistance:** See Coatings Applications section in this chapter.
- **Other optical characteristics:** These are also measured in multiple ways, although a common approach is to prepare a vinyl masterbatch and to determine the performance of the material in this exhibit. Other matrices are also used. The values are reported differently by the various producers (Harper and Modern Plastics 1999).

Paper

The information on paper is taken from Hagemeyer (1997).

- **Abrasion:** A measure of the degree to which a filler leads to the dulling of slitter knives and other equipment used in paper processing. Abrasion is generally measured by determining

the amount of metal removed from a screen that is placed into an aqueous dispersion of the filler and rotated several hundred thousand times to simulate blade movement. Another measurement used by some producers is a needle penetration test, wherein lab-generated paper samples are stacked and a needle is moved in and out of the stack several hundred thousand times. The mass loss of the needle is used as a gauge of abrasiveness of the filler employed.

- **Color, pH, and resistance:** See Coatings Applications section in this chapter.
- **Lightfastness:** The degree to which photobleaching occurs in a paper laminate. In such a system, there is neither oxygen nor water available to allow the occurrence of TiO₂-mediated photochemistry. As such, free radical degradation does not play a major role in these applications. The photoreduction of Ti(IV) to Ti(III) can occur, however, leading to a phenomenon called *graying*. The resistance of a specially treated titania pigment to this phenomenon is called *lightfastness* and is measured in an authentic laminate exhibit exposed to intense UV light for a prescribed period. The color change after bombardment is used as the determinant of lightfastness.

Finishing Processes

The front end of the two major commercial processes was previously described. The so-called finishing steps include unit operations that allow the construction of the surface architecture of the finished pigment particles commensurate with the intended end uses of the materials.

In the finishing process, the surface of the titanium dioxide pigment particle is modified via inorganic and/or organic surface treatments to induce requisite behaviors in end-use applications. Inorganic surface treatments are generally applied by deposition in an aqueous environment, usually in a stepwise manner. Photochemical stability is generally induced by coherent encapsulation of the pigment particles with hydrous silica. Because the resulting silica surface does not exhibit good dispersion performance or flocculation resistance, the silica jacket is typically covered by a layer of hydrous alumina. Some processes include a slurry milling step prior to surface treatment to ensure that the feedstock is fully deagglomerated and will therefore provide a more uniform core particle dispersion for the subsequent deposition reactions.

The deposition reactions lead to the formation of ionic species that must be removed from the pigments to ensure proper performance of the final product. As such, the materials are filtered to remove the ionic materials, dried, and then ground to remove any agglomerates formed during the drying step. The processing of the material as a dry pigment is complete at this stage. For purposes of use in waterborne applications (e.g., latex paints or paper coatings), the dry product may be slurried in water and stabilized with dispersants to yield a product that can be pumped directly into downstream equipment for use as a raw material.

End Uses, Applications, and Markets

The three major market segments for titania pigments are coatings, polymers, and paper. The important subsegments for these are as follows:

- Coatings—automotive, industrial, powder, architectural, special purpose
- Polymers—polyolefins, polyvinyl chloride, engineering resins
- Paper—wet-end applications, paper and paperboard coatings, laminates

The specialty segment includes everything from welding rods and shoe polish to toothpaste and solid rocket fuels. This is considerably smaller in volume than the three major segments. A specialty segment of particular importance is the use of titania pigments to deluster polymer fibers, particularly polyamides and polyesters. A segment related to coatings but generally discussed separately is the use of titania pigments in ink applications.

Generally speaking, the largest applications for titania pigments in all three segments include opacity and the protection of finished goods from UV radiation.

Using titania pigments in coatings allows high opacity to be obtained at nominal cost. In addition, exterior coatings (those exposed to the natural elements for the life of the article) are protected from the UV component of solar radiation by the pigment. Differing levels of durability (discussed earlier) can be used as a function of the expected service use and lifetime of the article being painted. For example, an interior flat paint will not typically be exposed to a substantial amount of UV radiation. As such, there is no reason to use a titania pigment that has been surface-modified to induce long-term stability to UV. Conversely, a material used in formulating an automotive topcoat high-gloss paint will need to have the best possible long-term performance in the face of the full brunt of nature. In this case, special surface modifications are made to the titania pigments used in the applications to ensure extended performance in this aggressive end use (Christensen et al. 1999).

Titania pigment use in polymers can be quite diverse—from the coloration of the ubiquitous white plastic shopping bag to the protection of vinyl siding and window profiles in home construction (Holtzen and Reid 2004). White roofing materials also contain titania pigments, as do many types of packaging materials and agricultural products. Applications in polyolefins are by far the largest-volume use in the polymer segment, with applications in vinyl second, and uses in so-called engineering resins (a term used to include a vast number of polymers, including essentially anything that is not either a polyolefin or a vinyl resin) applications third (Abel 1999; Cho and Choi 2001).

Titania pigment use in paper and paper laminates differ greatly in their performance requirements. They have been supplanted in many so-called wet-end applications, in which the pigment is added directly into a sheet of paper to provide opacity and brightness, by calcium carbonate. Much higher loadings of the latter are required because of a much lower refractive index (~1.63) versus rutile (~2.73) or anatase (~2.5).

In paperboard coatings, such as those used for cereal and beverage packaging, coatings similar in some ways to interior flat house paints are used to provide an opaque surface with very high brightness and excellent printability and print contrast. This is applied directly to the board in a high-speed continuous process.

Paper laminates require lightfastness. Color stability of the final laminate article is not possible without good performance in this regard. Many paper laminate formulas contain between 30% and 40% by weight titania pigment, and as such the performance of the laminate is strongly affected by the performance of the pigment used.

Competitive Alternatives

Because of the almost unique combination of properties of titania pigments—high refractive index, lack of toxicity, geological stability, high brightness—a direct not-in-kind replacement is not feasible in many end-use applications. For certain applications, it has been possible to supplant the use of titania pigments either with greatly increased loadings of a material with a much lower refractive index (e.g., calcium carbonate in wet-end paper applications)

or by substituting the hiding power of air voids (e.g., certain BOPP [biaxially oriented polypropylene] film applications).

Much effort has been expended over the last 50 years in attempting to develop and commercialize substitutes for titania pigments. Thus far, these efforts have been thwarted by higher costs, toxicity concerns, or difficulties in controlling the chemistries involved.

Environmental Considerations

Converting titanium-bearing ores into titania pigments requires removing all elements except titanium from the feedstocks during processing. The remaining materials will obviously be produced to a greater or lesser extent as a function of the titanium content of the ores. Managing the resulting material stream is handled in a number of ways as a function of the manufacturing process used and of the available end uses for the materials produced.

The largest component of this material stream is iron, particularly so when ilmenite is used as the feedstock or as a substantial portion of the feedstock. Some sulfate-process operators convert the iron to iron sulfate. This material can then be used as a soil adjuvant; as an additive to fertilizers, concrete, and other building products; as a flocculant for water purification; and as a source of iron for other manufacturing processes. Chloride process streams are typically smaller because of the use of higher-grade feedstocks, but substantial amounts of secondary materials (iron again being predominant) are generated nonetheless. Some of these materials are used in the manufacture of iron oxide pigments, whereas ferric chloride is also used as a flocculant for water purification.

The various producers exercise a variety of options for handling the portion of the secondary stream for which markets are not available. Chloride and sulfate producers can neutralize the acidic streams and landfill the resulting solids. The solids can also be roasted to produce iron oxides that can be stored or consumed by the steel industry. Deep-well injection of the secondary stream can also be practiced. Developing new means of addressing secondary component streams is an ongoing concern for all producers.

Trends and Opportunities for Titanium Dioxide

Growth in consumption of titania pigments continues to track or exceed GDP growth rates and is expected to do so for the foreseeable future. As such, increased consumption rates are noted in developing economies, particularly in Asia, Central and South America, and Eastern Europe. No substantive not-in-kind replacements with acceptable economics have been identified for pigmentary titanias, although this is always a possibility.

Major producers continue to develop new surface architectures for high-performance titania pigments. Synergic opportunities exist as new polymers, polymer blends, and alloys are introduced, which is also true for new coatings resins and paper chemistries.

One of the more fascinating aspects of the future of titania pigments actually lies in the nonpigmentary arena—namely, in nanotechnology. Many small companies and major multinational chemical companies are performing research in this field. Although it is unlikely that the volumes associated with these materials will ever challenge the enormous base applications of titania pigments, the value in use of the materials will be quite high on a unit basis. Some of the more interesting fields in which work is ongoing are covered in work by Kellar, Herpfer, and Moudgil (2003).

Refractories

Charles E. Semler

INTRODUCTION

The word “refractory” means obstinate, stubborn, or resistant to heat. According to the American Society for Testing and Materials (ASTM), refractories are nonmetallic materials with chemical and physical properties that make them applicable for structures, or as components of systems that are exposed to environments $>538^{\circ}\text{C}$ ($>1,000^{\circ}\text{F}$). In addition, refractories are used in applications $<538^{\circ}\text{C}$ ($<1,000^{\circ}\text{F}$), such as acid treatment (pickling) tanks; high-pressure hydrometallurgical autoclaves; chutes and ducts for transferring abrasive, granular materials; some cyclones and drying ovens; and more.

Refractories are the “backbone of industry” because they are essential for *all* production of important commodities worldwide such as iron, steel, cement, glass, aluminum, copper, nickel, brass, chemicals, ceramics, and petrochemicals. For this reason, the products, technology, and services of the refractories industry are a major source of support for the world’s economy. But despite their great importance, refractories are largely unknown to most people, which means that the refractories industry works anonymously as a silent partner that enables most traditional manufacturing industries to operate efficiently and profitably. This point is emphasized by the title of a book published about the history of the U.S. refractories industry, *Refractories: The Hidden Industry* (Krause 1987).

Importance of Raw Materials to Refractories

Raw materials have been, and continue to be, critically important to the refractories industry. These materials play a key role in the commercial and technical aspects of the business, such as storage, batching/mixing, product quality, properties, innovation and advancement, and profitability. Consequently, refractory companies continually search the world to locate, maintain, and enhance their raw materials supplies. Historically, refractories were first manufactured only from mined earth materials, such as clays, fireclay, sand, quartzite, schist, and others. As the knowledge and technology advanced, the usage of many other natural raw materials, such as bauxite, kyanite/sillimanite/andalusite, chrome ore, magnesite, dolomite, limestone, novaculite (silica), and zircon has increased. But over time, because of the need for higher purity and better refractoriness (i.e., improved high-temperature properties), there has been increased usage of beneficiated, processed, and synthetic raw materials, such as tabular alumina, seawater and fused magnesia, sintered and fused alumina, sintered and fused spinel, sintered

and fused magnesia-chrome, fused alumina-chrome, and sintered and fused zirconia, among others.

Classification of Refractories

Refractories are classified on the basis of the raw materials (natural, beneficiated, and synthetic) that are used. The main categories are fireclay, alumina, silica, basic (magnesia [MgO] and calcia [CaO]), insulating, and carbon, along with others such as zirconia, alumina-chrome, spinel (a complex oxide of magnesia and alumina [$\text{MgO}\cdot\text{Al}_2\text{O}_3$]), and nonoxides (e.g., silicon carbide [SiC], boron nitride [BN], aluminum oxynitride [AlON]). Specific classifications of refractory products can be found in the ASTM standards (ASTM 2005). Further description of the refractory categories was previously presented by Trostel (1994).

The relevant ASTM standard classifications are

- C27-98(2002): Standard Classification of Fireclay and High-Alumina Refractory Brick
- C155-97(2002): Standard Classification of Insulating Firebrick
- C401-91(2000): Standard Classification of Alumina and Alumina-Silicate Castable Refractories
- C416-97(2002): Standard Classification of Silica Refractory Brick
- C455-97(1999): Standard Classification of Chrome Brick, Chrome-Magnesia Brick, Magnesia-Chrome Brick, and Magnesia Brick
- C467-97(2002): Standard Classification of Mullite Refractories
- C545-97(2002): Standard Classification of Zircon Refractories
- C673-97(2003): Standard Classification of Fireclay and High-Alumina Plastic Refractories and Ramming Mixes

Several other refractory classifications should be mentioned. For more than 60 years, the U.S. Department of Commerce has classified refractories as clay and nonclay types in its annual statistical reports of refractory production and value. These categories are a historic relic of the past when “clay-based” refractories were the most important products in terms of both tonnage and value; today, however, they are less significant. Refractories technology has seen major advances over the decades, so today the clay and nonclay categories would be better termed “traditional-type” and “value-added-type” refractories, respectively.

Other refractory classifications that were widely used in the past were acid, basic, neutral, and special (Coxey 1950). Acid

refractories were those composed of silica, alumina, and aluminasilica. Basic refractories were composed of alkaline earth oxides, such as dolomite, magnesite, and lime. Neutral refractories were those that did not readily react with acidic or basic materials, such as chrome, SiC, carbon, and so forth. Special refractories were those that did not fit into the other categories (e.g., titania, zircon, zirconia, and nitrides). Over time, with the increased development of various mixed types of refractories, these chemical distinctions have become less clear and harder to apply, so the usage has declined. The basic category, however, is still accepted and widely used in reference to refractories based on magnesium (Mg), lime (Ca), and magnesium and lime (Mg-Ca).

Physical Form of Refractories

Because of the thousands of different applications and the requirements for refractories in many industries, a wide variety of physical forms are manufactured, as follows

- Brick and special shapes (shaped refractories)—fired, unfired, fusion cast, insulating
- Monolithic products (unshaped refractories)—castables, gunning mixes (dry and wet), ramming mixes, dry vibratable mixes, plastics, mortars
- Fibrous refractories—blanket, modules, board, paper, rope, vacuum-formed
- Miscellaneous products—e.g., crucibles, kiln setters, electrodes, brake pads

Manufacturing of Refractories

The main steps involved in the manufacture of bricks and monolithic (e.g., castable) refractories—the two main product types—are as follows

Brick Refractory	Monolithic Refractory
Obtain raw materials	Obtain raw materials
Prepare/treat materials	Prepare/treat materials
Store materials	Store materials
Weigh/batch	Weigh/batch
Mix	Mix
Press and inspect	Package and quality control
Dry	Store/ship
Fire	
Inspect and quality control	
Store/ship	

The refractory manufacturing process involves many variables (workers, equipment, raw materials, and procedures) that must be understood and controlled to ensure that the products will be uniform and consistent and fully meet the user's needs and guidelines. As a result, all the refractory companies of the world devote significant time and effort to the monitoring and control of product quality to try to avoid shipping of f-quality products to customers. Statistical process control, ISO-9000, Six Sigma, or other manufacturing quality control practices are commonly used.

There is a basic difference between the brick and monolithic manufacturing procedures that should be noted—brick manufacture involves the additional steps of pressing, drying, and firing. The manufacture of bricks, then, involves more capital expense and quality control concerns than monolithic refractories, and as the refractory industry evolves to meet practical and economic needs, these issues will help promote increased manufacture and use of monolithic refractories at the expense of bricks. The trend toward

increased use of monolithic refractories is already in progress as described in the Refractory Production and Usage Trends section of this chapter.

Testing of Refractories

Because of the many variables involved in the manufacture of refractories (such as multicomponent raw materials, coarse through ultrafine particle sizing, contamination possibilities, mixing efficiency, firing time and temperature, and many more), testing is necessary to ensure uniform, consistent production. In addition, tests are needed to compare “equivalent” products from different manufacturers, to determine the effects of service, and for R&D, among other purposes. Most countries have organizations that develop standard refractory tests. In the United States, ASTM develops and issues the standard refractory tests. Internationally accepted test methods are available from the International Organization for Standardization (ISO).

The evaluation of refractory properties is very important, especially with the increase in global sourcing of refractories from the worldwide marketplace. A product data sheet, which shows the general properties obtained by standardized tests, is available for every commercial refractory product. Although these property data sheets allow a general comparison of refractories from different manufacturers and are widely used, it is not appropriate to use them for purchase specification purposes. For detailed product comparisons, and the establishment of purchasing specifications, it is important to obtain the most current data and statistical ranges from the refractory manufacturer(s).

The general categories of refractory tests, which are used individually or in combination for a wide variety of purposes, are as follows

- Chemical analysis—bulk and/or localized, specific analyses
- Chemical resistance—slag, molten metal, acid, alkalis, gas species
- Physical properties—porosity, density, specific gravity, permeability
- Mechanical properties—strength (room temperature and hot), fracture energy, abrasion resistance, modulus of elasticity, crack propagation rate
- Thermal properties—expansion/shrinkage, creep, conductivity, refractoriness, resistance to rapid temperature change (thermal shock)
- Technical modeling—image analysis, finite element analysis, fractal analysis

It is significant to note that any given refractory type (e.g., 90% alumina brick, mullite brick, low cement alumina castable, MgO–13% C brick, and graphite plastic) from different manufacturers will not be identical in composition or properties, as opposed to other industrial commodities (e.g., 310 stainless steel) that are virtually identical from any manufacturer. Consideration of the variation in refractories (between manufacturers and lot-to-lot), must be included in lining design, product comparison, purchase specifications, bid/quote evaluation, and acceptance criteria, although the need is frequently not known or overlooked. The characterization testing of refractories, including quality control, is extremely important for the optimization of refractory performance.

REFRACTORY STATISTICS

The steel industry is by far the major consumer of refractories, as indicated by Table 1.

Figure 1. U.S. annual production of steel and refractories

Table 1. Two breakdowns of the global refractories market

Industry	Mosser and Karhut 1999, %	Meier 2004, %
Steel	70	63
Cement and lime	6	14
Chemicals	6	NR*
Ceramics	5	NR
Glass	4	9
Nonferrous metals	3	9
Other	6	5

* NR = not reported.

Historically, there has been a relationship between the annual production of steel and refractories. Figure 1 shows the annual production of steel and refractories in the United States since 1970 (International Iron & Steel Institute 2001–2003; U.S. Department of Commerce 1970–2002). In 1979, the maximum refractory production in the United States was about 6 Mt, and annual production has now decreased by roughly 50%. Generally, in the past, when steel production increased, refractory production increased. But since about 1991, that direct relationship has changed, as there have been years when refractory production decreased despite an increase in steel production. Various factors are involved in this change, such as (1) more refractories are being imported; (2) refractories are continually being improved and last longer in service; and (3) since 1970, the rate of consumption of refractories by the steel industry in the United States and Japan has declined from 25 to 30 kg of refractory per ton of steel to about 8 kg/t (see Figure 2). It is expected that the refractory consumption rate by the steel industry will continue to decrease, albeit at a very slow rate. The data for Brazil and China indicate that their refractory consumption rates are decreasing and eventually will be very similar to those of the United States and Japan. And like the steel industry, the decrease in refractory consumption is occurring in other industries, such as cement, glass, and copper (Semler 2004), so this ongoing decrease in the refractory consumption rate must be included in the consideration of future refractory production requirements.

Figure 2. Refractory consumption trend: Steel industry

Figure 3. Annual value of clay and nonclay refractories in the United States

Figure 3 shows the annual value of the U.S. refractories market since 1990 (U.S. Department of Commerce 1970–2002). The total market value peaked in 1997 at \$2.57 billion and has declined each year since then, reaching \$1.74 billion in 2003. Figure 3 also displays a breakdown of the market value according to the two

Table 2. Price changes for selected refractory product types (1993–2003)

Refractory Product	1993, \$/t	2003, \$/t
Fireclay bricks	440	489
Insulating firebricks	914	1,300
High-alumina bricks	600	763
High-alumina castables	540	623
High-alumina plastic/ram	460	635
>88% alumina bricks/shapes	3,770	3,820
>88% alumina plastic/ram	1,140	1,220
MgO-C bricks	1,120	610
Zircon/zirconia bricks	6,400	6,830

refractory categories used by the U.S. Department of Commerce (i.e., clay and nonclay products, which were discussed previously). In recent years, nonclay refractories have accounted for a higher percentage (58%) of the annual market value than clay refractories. This trend correlates with the continuing advancement of refractories technology, including the usage of more synthetic, higher purity raw materials.

REFRACTORY PRICING

The overall average price per ton for refractories in the United States peaked at \$659 in 1995, but since then the price has decreased, reaching \$578 in 2002. These price-per-ton figures are derived from the U.S. Department of Commerce (1970–2002) figures for annual tonnage of production and the associated total market value.

Representative examples of the price change (US\$) for several refractory product types in the United States between 1993 and 2003 are given in Table 2.

REFRACTORY PRODUCTION AND USAGE TRENDS

Based on the ever-changing operations/requirements of the refractory users, including the constant demand for cheaper refractories, there are changing trends in refractory usage.

Figure 4 (U.S. Department of Commerce 1970–2002) shows the change in fireclay, high alumina, and magnesia-carbon refractory production in the United States since 1988. The data show that in the early 1990s the annual production of these products was stable or slightly increasing, but in the last 5 years, production has decreased. Figure 5 (U.S. Department of Commerce 1970–2002) shows the change in silica and magnesia-chrome refractory production in the United States since 1990. Except for an increase in production of these two refractory products in the mid-1990s, their output has decreased significantly since 1990.

Since the mid-1980s, there have been major advances in the properties and types of monolithic refractories, especially castables, and the installation technology has been improved (e.g., shotcasting/wet gunning). Based on improvements that have allowed the cement addition to be reduced, there are now multiple classes of castables:

- Conventional—15 to 30 wt % cement
- Low cement (LCC)—1 to 5 wt % cement
- Ultralow cement (ULC)—0.2 to 1 wt % cement
- No cement (NCC)

As a result, a wide variety of material options and installation methods are available for consideration. Because the performance and cost-effectiveness of castables can now be equivalent to or better than that of pressed/fired bricks and shapes, the production/use of castable refractories has continuously increased, as shown in

**Figure 4. U.S. refractory brick trends (alumina, fireclay, magnesia-carbon)****Figure 5. U.S. refractory brick trends (magnesia-chrome, silica)**

Figure 6. In Japan and the United States, the production of monolithic refractories has exceeded brick production since 1992 and 2000, respectively. This trend can be expected to continue because the ongoing R&D will further improve and advance the properties and practical utility of monolithic refractories.

ECONOMIC STATUS OF REFRACTORIES

The annual value of the world refractory market is estimated to be \$16 to \$18 billion, for a demand of 25 Mt or more. China is the major contributor to the world market with roughly \$5.5 billion in value and about 18.7 Mt of production in 2004 (Liu and Zhou 2004), which is about 6 times more than the United States production. The role of China as a manufacturer, exporter, and user of raw materials and refractories will continue to dominate the world scene. The world's main refractory companies in terms of annual sales are outside China—RHI Refractories, Cookson Group, and Saint-Gobain each have sales that exceed \$1 billion.

According to Barr et al. (1973), by any meaningful criteria, the refractories industry is fundamental to the functioning of the total economy and makes a highly significant contribution to both the total industrial activity and the generation of gross national product. So the refractories industry occupies a fundamental and strategic position in the structure of the U.S. (and global) economy, and any reduction in the output will tend to cause an equal proportionate reduction in the output and income of every other industry.

In summary, the economic impact of refractories worldwide is enormous. Without refractories, business and life as we know it today would simply not be possible (McCracken 2004). But the

Figure 6. Monolithic refractory market share (Japan, United States, and Germany)

overall economic impact of refractories on the national or global economy is not routinely monitored and tracked to provide a clear indication of their critical importance in industrial manufacturing. In the absence of such an indicator, they are relegated to a role of silent anonymity in the global marketplace, not unlike farmers who play the critical supply role in the food chain (the staples of human life), but are not fairly compensated for their products, in comparison with the value received by others later in the chain. Likewise, it could probably be documented that the refractory industry is not fairly compensated for the R&D, technical service, and the improved, more durable products that they continually provide to the users. The users, however, realize major benefits, including the opportunity to maintain and increase their output, enhance efficiency, and increase income and profitability. A win-win relationship would seem fair, in which the refractories industry is appropriately rewarded, rather than penalized, for continually providing improved products that result in reduced demand (sales) for refractories while allowing customers to realize significant practical and economic benefits.

The refractories industry has a long history of direct communications and interaction with customers, which in many cases involves daily, on-site collaborative work and the development of close personal relationships. To promote and develop an increased understanding of the value of refractories, the industry should better utilize its long and successful history of involvement with customers. In addition, the industry needs to fully explore the unlimited opportunities worldwide that are afforded by cyber-business, partnering, joint ventures, technical service needs, and currency fluctuations, among others. There might also be aspects of the Japanese system of "sister companies" and keeping the business in the family that could be developed to advantage elsewhere in the world.

Despite the ongoing decline in refractory production and market value, new players can still find many opportunities to participate and succeed in business by focusing on the requirements for new technology/processes, offering creative solutions to customer's problems and needs, recognizing niche market opportunities, developing novel/improved products, and many other options.

REFRACTORIES ADVANCEMENT AND OUTLOOK

The refractories industry has changed significantly in recent years because of domestic and global factors such as the decreasing consumption of refractories, consolidation and downsizing, reduction of manufacturing capacity, globalization of the marketplace, legal and financial liabilities, and the decline of refractories education. It

is not expected that the activity level or business will ever return to the levels of earlier years. Instead, the refractories industry will continue to evolve, to maintain and enhance the business success in conjunction with the challenges and competitive pressures of the new global marketplace, becoming leaner, more efficient, and more cost-effective. It is known that the need for refractories will continue for many decades, because they are essential for all traditional, and other, manufacturing industries. It is clear that many more improvements and innovations will emerge in the coming years, based on the past history of ongoing refractory advances, and even more attention will be directed to environmental, recycling, and safety and health issues.

Examples of some refractory R&D topics that can be expected to yield advances in the coming years are

- Raw materials, additives, particle sizing
- Engineered microstructures
- Castables (carbon-containing, rheology, dryout, additives, etc.)
- Monolithic refractory installation
- Spinel (primary, in-situ, and prescription types)
- Non-oxide and composite materials
- Modeling and sophisticated engineering analysis

As stated by T. Vert of Dofasco Steel, Hamilton, Ontario, Canada (personal communication), "Refractories are moving from a commodity bought by the pound, to an engineered material that must be designed differently for every customer." Experience has shown that focused R&D can result in significant improvements, specific to a process or application, but there must be an economic reason to undertake such projects because they commonly involve smaller markets with smaller monetary returns. Refractory users need to understand that many more refractory advances are possible, and for specific, niche-type applications, if they are willing to pay in accordance with the benefits that will result from prescription-designed refractories.

As W.H. McCracken has commented, "Refractories companies are not going out of business. Someone will always be around to produce them, somewhere, and someone will always be using them. A past president of Harbison-Walker Refractories Co. always said that refractories are not going to become obsolete and disappear, EVER" (O'Driscoll 2004).

Soil Amendments

Gretchen K. Hoffman and George S. Austin

INTRODUCTION

Soil amendments are defined as any natural or synthetic soil-conditioning materials that are worked into the soil or applied on the surface to enhance plant growth. This term commonly refers to added materials other than those used primarily as fertilizers (SSSA 2004), which are discussed in the Fertilizers chapter. Soil amendments mainly modify physical characteristics and microbial action, or change the pH of a soil, or both, rather than directly supplying nutrients to plants. They give soil the needed physical properties to allow plant growth, fight erosion, or retain water. Although some soil amendments do provide nutrients in addition to altering the physical, biological, or chemical characteristics of soil, this is not their primary purpose.

Both inorganic and organic materials are used as soil amendments. Several inorganic soil amendments have been used since the early twentieth century: limestone, lime, and similar calcium-rich carbonates and oxides for acid soils, and calcium sulfate (gypsum) and native or uncombined sulfur for alkaline soils. The use of these amendments (limestone, lime, gypsum, and sulfur) or their equivalents has been studied and documented in many basic soils studies (see, for example, McCaslin and Boyle 1980). Only the most commonly used and those that appear to have potential to become commonly used are discussed in this chapter. In some cases—such as perlite and vermiculite—the soil amendment application covered in this chapter is only a minor end use of a particular mineral or rock, and other chapters in this book offer detailed discussions of these minerals and rocks.

Peat is the principal natural organic soil amendment, but manure, both as a fertilizer and soil conditioner, is used in every part of the world. In less-developed countries, manure is the primary soil fertilizer/conditioner. An organic-rich material designated as *humate* or *leonardite* has been marketed as a soil amendment for many years and is addressed in this chapter.

Other materials (such as synthetic products) are not discussed here but can be found in the Soil Science Society of America's (SSSA) special publication 7, *Soil Conditioners* (Stewart 1975). These products include bitumen emulsion, polyacrylamide, polyvinyl acetate, polyvinyl alcohol, bentonite, nonionic surfactants, and natural mulches. Zeolites can be added to the list of miscellaneous soil amendments (McCaslin and Boyle 1980), as can calcium chloride (Pressler and Pelham 1985), sulfuric acid, ferric and ferrous sulfate, aluminum sulfate, ammonium polysulfide, calcium polysulfide,

and ammonium bisulfite (Stromberg and Tisdale 1979). Sludge is not considered a soil amendment because it has properties more consistent with fertilizers. All these other materials, which account for a very small part of the volume and value of soil amendments used, are discussed only briefly.

Soil Types

Soils amenable to treatment with amendments are separated into five general categories: acid, saline, alkaline (pH >7.0), saline-alkali, and calcareous (soil containing sufficient free calcite [CaCO_3] and other carbonates to effervesce visibly or audibly when treated with cold 0.1 M hydrochloric acid [HCl]; SSSA 2004). Optimum plant growth occurs for a great majority of crops and plants at a soil pH of 6 to 7 (neutral). Acid soils (pH 3.5 to 6.0) are created when calcium is leached by relatively high rainfall, which lowers the soil pH, producing acid. Aluminum also comes into play to the extent that highly acidic soils can result from aluminum saturation. Soils become acidic because the cations of soil colloids, primarily calcium, are replaced by hydrogen ions. This involves ion exchange and other adsorption reactions that are associated with the colloids. The total soil acidity is made up of two components—active and exchangeable (reserve) acidity. Active acidity, which is the H^+ ion concentration in the solution phase, is measured by pH. Exchangeable acidity is the hydrogen (H^+) and aluminum (Al^{3+}) ions that are chemically bound to cation-exchange sites on clays and organic matter. Exchangeable acidity makes up the greatest portion of total acidity (SSSA 2004; Beegle and Lingenfeller 1995). Soil exchangeable acidity determines the amount of aluminum and hydrogen that can be replaced by an unbuffered salt solution such as potassium chloride (KCl) or sodium chloride (NaCl; SSSA 2004). Because clay minerals and organic particles have large surface areas, they usually have much higher total acidity than sandy soils, and it takes a larger volume of neutralizing soil amendment to raise the pH of these soils.

A saline soil is one having an electrical conductivity of the saturated extract (EC_e) of more than 4 millisiemens* per centimeter (mS/cm) at 25°C and an exchangeable sodium percentage (ESP)[†] of less than 15 (Stromberg and Tisdale 1979). Ordinarily, the pH of

* A millisiemens is equivalent to a millimho.

† The total amount of exchangeable cations a soil can retain is called the cation-exchange capacity (CEC) and is usually expressed in milliequivalents per 100 g of soil. The ESP is the ratio of the exchangeable sodium to the CEC.

Table 1. Soil amendments statistics (2003)

Soil Amendment	Producing States (2003)	U.S. Consumption, t	Average Price, \$/t	Exports to the United States
Agricultural limestone and dolomite (Tepordei 2003)	34 states (top producers are Alabama, Kentucky, Missouri, Nevada, Ohio, Pennsylvania, and Texas)	Limestone, 10×10^9 ; Dolomite, 1.38×10^9	Limestone, 5.84; Dolomite, 11.16	Canada, Mexico
Gypsum (Olson 2004)	17 states (top producers are Oklahoma, Texas, Nevada, Iowa, California, Indiana, and Michigan); 25 companies	33×10^9 uncalcined gypsum; 1.0×10^9 for agricultural purposes	6.90	Canada, Mexico
Perlite (Bolen 2004)	7 states (Arizona, California, Idaho, Nevada, New Mexico, Oregon, Utah); 8 companies	0.712×10^9 ; 13% of total end use	37.36	Greece
Vermiculite (Potter 2004)	2 states (South Carolina and Virginia); 2 companies	0.110×10^9 exfoliated; agricultural, insulation, and other, 73% of end use	143 (concentrate)	South Africa, China
Peat (Jasinski 2003, 2004)	16 states (top producers are Florida, Michigan, and Minnesota)	1.39 million, 5% of total domestic production for horticultural use	Sphagnum moss, 63.20	Canada (sphagnum)
Humate	3 states (North Dakota, Utah, New Mexico)	$\sim 80,000$ t	90–450*	Canada

* Range is for wholesale price.

these soils is less than 8.2. A saline soil can be recognized by the accumulation of white salts on the surface. The chief cations are sodium (Na^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}), and the chief anions are chloride (Cl^-) and sulfate (SO_4^{2-}), with lesser amounts of nitrate (NO_3^-) and carbonate (HCO_3^-). Soluble carbonate is rarely present in saline soils.

An alkali or sodic soil has an ESP of greater than 15 and an EC_e of less than 4 mS/cm. The soil pH is usually greater than 8.5 and may reach 10 or more. The high ESP of alkali soils causes them to lose their structure. Because of the destruction of soil aggregates, which is responsible for the presence of large pores, the soils become almost impervious to water and air. Root penetration is impeded, clods are hard, and seedbeds are difficult to prepare. Saline-alkaline soils are both saline and alkaline (i.e., they have an EC_e of greater than 4 and an ESP greater than 15). Their physical properties are similar to saline soils as long as excess salts are present. As soon as they are irrigated and the soluble salt content of the surface horizon is reduced to a low level, they act as alkaline soils. Calcareous soils contain free calcium carbonate throughout the profile. They are nonsaline and have a pH ranging from about 7.5 to a maximum of 8.2. The EC_e is below 4 mS/cm and the ESP is usually less than 10.

Many crops exhibit symptoms of nutritional deficiencies on some alkaline and calcareous soils. This is often attributed to the failure of the plant to assimilate some of the nutrient elements, such as phosphorus, iron, copper, manganese, and zinc—all of which are micronutrients except phosphorus. Deficiencies of these elements are sometimes exhibited by a yellowing of the leaves, often termed *lime-induced chlorosis*. This is an oversimplification of a more complex problem. It must be recognized that crops grown on many calcareous soils with a pH of 8.0 do not show these symptoms. The solubility, however, increases by a hundred- to a thousandfold from a pH of 8.0 to 7.0. Micro nutrient deficiencies may also exist in acidic soils. In such cases, they may be true deficiencies and not a case of the plants being unable to absorb the nutrients because of a high soil pH (Stromberg and Tisdale 1979).

STATISTICS

Many of the soil amendments are sold by the companies that mine, process, and market the product for many end uses including soil amendments. For several of the soil amendments such as limestone, perlite, vermiculite, and peat, the producers are members of trade associations that promote the product and supply information to

both the supplier and buyer. Table 1 outlines production, consumption, price, and major exporting countries for the principal soil amendments.

A general barrier to entry for any soil amendment is distance to market. If the deposit is not close to a market area, it will not be able to compete. Exceptions exist, however, such as with peat imported from Canada to the United States.

CLASSIFICATION

Soil amendments can be divided into categories—those that are primarily used to change the soil's pH and those that are added to change the soil's physical characteristics. Some soil amendments are also used as carriers for fertilizer or insecticides. Table 2 lists the significant chemical and physical properties of the inorganic and organic soil amendments discussed.

Inorganic Soil Amendments

Limestone and Dolomite

Limestone and dolomite, often referred to as agricultural lime or aglime, are the most common carbonate rocks used as soil amendments to neutralize the acidity of soil and promote plant growth. In the Fertilizers chapter, limestone and dolomite are discussed as sources of calcium and dolomite as a source of magnesium for plant growth. Four factors are important in aglime quality: chemical purity, speed of reaction, magnesium content, and moisture (Beegle and Lingenfeller 1995). Chemical purity determines the amount of soil acidity the material can neutralize, expressed in terms of calcium carbonate equivalents (CCE). Pure calcite is assigned a CCE of 100, although pure dolomite [$\text{CaMg}(\text{CO}_3)_2$] has a theoretical value of 108.6. Dolomite is 8.6% more effective than calcite as a neutralizer because the molecular weight of magnesium (MgCO_3) is 84.32 as compared to CaCO_3 , which has a molecular weight of 100.9. Because of the difference in solubility of dolomite in contrast to limestone, however, it takes longer to neutralize with pure dolomite than with pure limestone. The composition of limestone and dolomite varies greatly because of impurities such as clay minerals, quartz, and organic matter. It is also very important to establish the exact chemical composition of the soil before making a decision about the liming material. Liming materials of less than 50% CCE would require too much material to reduce the acidity of the soil.

Although most agricultural liming today is achieved with pulverized limestone, many farmers still use ground quicklime (CaO) and hydrated lime [$\text{Ca}(\text{OH})_2$], particularly in the U.S. mid-Atlantic

Table 2. Major soil amendment properties

Soil Amendment	Main Use	Chemical Attributes	Physical Attributes
Limestone – Dolomite (Beegle and Lingenfeller 1995; USDA 1999a)	Agriculture, to treat acidic soils	Neutralize by base exchange Ca and Mg cations	Increases soil tilth; improves microbial activity
Gypsum (Olson 2004; Harben 2002)	Agriculture, to treat alkaline, saline, and alkaline-saline or calcareous soils	Calcium replaces sodium ions in clay soil. Source of calcium and sulfur	Improves permeability, drainage, aeration
Vermiculite (Harben 2002)	Horticulture	High CEC. As material breaks down, it is a source of potassium and magnesium	Improves workability, aerates soil, acts as a carrier for fertilizers and pesticides
Perlite (Harben 2002)	Horticulture	Chemically inert, low CEC	Retains two to four times its dry weight in water, aerates soil, resists compaction
Zeolites (Hall 1998; Harben 2002)	Agriculture, horticulture	High CEC, low sodium, low clay content	Open structure; retains moisture and nutrients
Fly Ash (EPRI 2002; Mittra et al. 2003)	Agriculture	High calcium; neutralizes acidic soils	Improves soil texture. Sandy soils: improves water retention; clayey soils: increases porosity
Humates (Hoffman, Barker, and Austin 1995; Wallace 1998)	Agriculture, horticulture	High CEC	Helps retain nutrients and moisture
Peat (Wallace 1998)	Agriculture, horticulture	Decomposed organic material, high CEC; provides acidity	Acts as anticompaction agent, helps retain water and aerate soil

states. Lime costs more than limestone on an equivalent calcium oxide basis, but it reacts faster, neutralizing soil acidity rapidly so that crop yields do not suffer. In some sandy soils, dolomitic lime is used because of persistent magnesium deficiencies. Because agricultural lime serves as a source of calcium and magnesium, the magnesium content can vary depending on the source. A magnesium analysis is necessary to determine the percentage of magnesium content. The moisture content of agricultural lime is important because the product is sold by weight. Other products that are used as aglime include lime (burnt or lump) and quicklime as a form of calcium oxide; hydrated, slaked, or builder's lime as calcium hydroxide; marl or shells as calcium carbonate; and slag (CaSiO_3).

Speed of reaction to neutralize the acidity is determined by the material's fineness. The finer the limestone is ground, the greater the increase in solubility and the faster it will react with the soil. Agricultural lime particles larger than 20 mesh react slowly in soil, showing little neutralizing effect within 2 to 3 years (Beegle and Lingenfeller 1995). Material of 100 mesh reacts within a practical time (<1 year), but the cost of grinding must be considered. A material with 95% passing through 20-mesh, 60% through 60-mesh, and 50% percent through 100-mesh screens is considered adequate (Beegle and Lingenfeller 1995). Aglime contains both fine and coarse material, and the percentage can vary from producer to producer. Many states require that 75% to 100% of the material passes an 8- to 10-mesh screen and that 25% passes a 60-mesh screen. In some southern states, lime laws require that no more than 10% remain on a 10-mesh screen and no more than 40% can remain on the 60-mesh screen. At least 50% must pass through the 60-mesh screen (USDA 1999a). The CaCO_3 and MgCO_3 equivalent or content is of major significance for agricultural use.

Agricultural lime is one of the many products marketed by crushed-stone operators. At a typical quarry in relatively flat-lying strata, the limestone or dolomite bed near the surface is stripped of overburden and quarried in a conventional manner, then crushed and screened to a appropriate sizes at a nearby plant. Specifications for agricultural liming materials are outlined in American Society for Testing and Materials C602. The fineness of aglime is classified

Courtesy of Martin Limestone, Inc.

Figure 1. Spreading crushed limestone on a field before spring planting

by the minimum percentage passing and remaining on the 8-mesh (2.36-mm) and 60-mesh (250- μm) screens. The 8-mesh is used to control the upper limit on the amount of coarse particles in the product. Specifications for CCE are set for burnt lime (not <140 CCE), hydrated lime (not <110 CCE), and limestone (not <80 CCE). The maximum size as regulated by the state varies but is generally between 8 and 20 mesh. The smallest size fraction is <120 mesh and the optimum size fraction is 60% to 40% <60 mesh (B. W. Remick, personal communication).

Agricultural limestone is dispersed onto the surface to raise the pH in pasture soil (Figure 1). For deep-root plants, it is disked into the soil to a maximum depth of about 15 cm. From 1.1 to 1.5 t/ha (0.11 to 0.15 kg/m^2) is considered the maximum amount of agricultural lime that should be applied to soil during a year (B.W. Remick, personal communication). For the most part, agricultural lime is

marketed to large operations in bulk form; however, packaged lime can be found at nurseries for home gardening. Lime is also marketed in a pelletized form. The fine lime particles are bonded together with lignosulfonates. The use of pelletized lime in agricultural applications is limited by the extra cost.

Several industrial by-products can be used as substitutes for aglime. Air-cooled blast furnace slag or granulated blast furnace slag, which are products of iron and steelmaking processes, have significant amounts of calcium and are potential substitutes for traditional sources of agricultural lime. Cement kiln dust has been used successfully as a liming agent for acidic soils. In some Canadian provinces, cement kiln dust is used to maintain soil fertility by restoring soil pH acidified by fertilizers while supplying potassium and sulfur (Risdale 1994).

Gypsum

Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is the most common of the naturally occurring sulfate minerals. Crude gypsum is marketed for use in cement, agriculture, and fillers. Since the eighteenth century, gypsum has been used as a soil conditioner in Western Europe and is used today in many parts of the eastern United States. It is a source of calcium and sulfur in the form of sulfate and can reclaim alkaline (high-sodium) soils by replacing sodium with calcium (see discussion in Fertilizers chapter). As a soil amendment, gypsum neutralizes sodic soils by replacing the sodium with calcium. The displaced sodium must then be leached from the soil by watering to a depth greater than the root zone. The addition of gypsum also improves the permeability of argillaceous materials, and improves aeration, drainage, and penetration of water (Harben 1995). Gypsum also provides sulfur and catalytic support for maximum fertilizer utilization and leguminous productivity (Pressler 1985). Unlike lime, gypsum is effective in the amelioration of subsoil acidity (Levy and Sumner 1998). Lime does not move readily into the subsoil and is costly to incorporate. Gypsum has greater solubility than lime and can migrate into the subsoil and increase the calcium in the subsoil. Because gypsum has little or no effect on the soil pH, it is the preferred calcium source to remediate high-sodium soils (Zublena, Rubin, and Crouse 1995). The calcium in gypsum also promotes clay flocculation, which can reduce the tendency of soils to form seals, surface crusts, and subsoil hardpans (Levy and Sumner 1998).

Agricultural gypsum requires little processing and is sometimes referred to as "land plaster." Gypsum is extracted from surface pits and underground mines, then milled to different sizes, depending on the end use. It is typically used in large agricultural operations and delivered in bulk by truck to the farmer. Gypsum is also pelletized to decrease the amount of dust generated during application to croplands or turf and is available in bags or in bulk.

Uncalcined gypsum can vary in purity, but 70+% CaSO_4 (calcium sulfate) is required for application as a soil conditioner. For agricultural use, grinding to a fineness of 80% to 90% through 100 mesh is preferred (Harben 2002). Some low-grade ore is upgraded by log washing, sink flotation, or selective crushing and screening, both wet and dry. These methods produce a commercial gypsum product of 80% $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ or higher (Pressler 1985). The requirements for agricultural gypsum are not very rigid, but the $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ content or equivalent is of major significance. To reclaim alkaline soils, gypsum should be incorporated into the soil at a rate of 4.48 to 6.75 t/ha (0.45 to 0.67 kg/m²). If the goal is water penetration, gypsum can be added using the broadcast method (2.24 to 4.48 t/ha). Application rates to promote the movement of calcium into the subsoil in low-calcium, acidic soils can be on the order of 6.7 to 8.06 t/ha. Solution-grade gypsum can also be added to the irrigation water to add gypsum to cultivated acreage.

Flue gas desulfurization (FGD) products (discussed in detail in the chapter on Flue Gas Desulfurization) and ground scrap wallboard material can be used as a substitute for gypsum in agricultural applications. Ground wallboard will still have paper in the product, but this can be broken down by soil organisms. The phosphate fertilizer industry also produces large quantities of a high-purity, fine-grained gypsum by-product termed "phosphogypsum." This material is not usable for agriculture because its uranium content makes it slightly radioactive.

Sulfur

A small amount of elemental sulfur is used as a soil amendment and as a nutrient. At times it is difficult to distinguish between sulfur as a nutrient and sulfur as a soil conditioner. As a conditioner, sulfur is used by itself or in combination with various nitrogen compounds to lower the pH in alkali soils, to improve water filtration, or both. This action, however, also improves the uptake of sulfur and the availability of certain micronutrients to the soil (Miyamoto 1998).

In agriculture, refined sulfur with a purity of 99.5% is ground and applied directly to the soil. Crude sulfur, formed into granules or pellets before grinding, or as fines separated from bulk sulfur, may also be used. In a few cases, sulfur in the form of sulfuric acid or as gypsum is used as a soil amendment.

Vermiculite

Finer-size grades of vermiculite are used as a plant-growth medium, chemical fertilizer, extender, anticaking agent, and carrier for pesticides and herbicides (Meisinger 1985). The high CEC, a result of vermiculites' platy structure, facilitates many of these applications (Strand and Stewart 1983). Vermiculite also has a high water-holding capacity because of its high surface-area-to-volume ratio, low bulk density, and almost neutral pH. As vermiculite breaks down, available potassium (5% to 8%), magnesium (9% to 12%), and calcium (<1%) are gradually released to the plants.

Vermiculite is similar to perlite in that it is shipped from the mine site in raw form and exfoliated at plants near market areas. Processing of vermiculite includes heating the raw material to 900°C to convert the water trapped between the structural layers to steam, which expands or exfoliates the material. The volume of exfoliated vermiculite is 15 to 20 times greater than that of the raw product. Vermiculite is produced in different grades for different applications. The grades are differentiated by bulk density and average particle size. The finer particle sizes (grades 3 to 5) have more surface area and are used for soil amendment applications. Expanded vermiculite is generally sold in bags and used in horticultural applications at nurseries and for home gardening. Vermiculite is often mixed with peat and other material and sold in bags as potting soil mix. A mixture of one third vermiculite and two thirds soil is recommended for heavy soils. Alternatives to vermiculite include peat and perlite, as well as sawdust, bark, and other plant materials (Potter 2004).

Perlite

The important properties of expanded perlite for use as a soil amendment are (1) chemical inertness, which results in the product remaining in the soil for a long time; (2) low CEC; and (3) a closed cell composition (bubbles) that resists compaction and enhances drainage. Perlite can retain two to four times its dry weight in water, giving it greater total inner porosity than sand. In addition, perlite aerates the soil, which allows air and moisture to get to the plant roots and is essential for optimum plant development. The uniform spherical size of expanded perlite resists compaction and increases

permeability and drainage of the soil. Perlite has many applications in hydroponics and soil-less growing media with peat. The Horticultural Committee of the Perlite Institute specifications for aggregate and horticulture are considered coarse grades that have 70% minimum +16 mesh or 1 mm. Fine and medium grades, however, are recommended for some horticultural applications.

Perlite deposits occur in remote areas, particularly in the western United States. This can be a barrier because of transportation costs and low value. Raw perlite is shipped by rail from the mine site in an unexpanded form to expansion plants located near market areas. Expanded perlite is 10 to 20 times the original volume of perlite. When flash-heated to 870°–1,000°C, the perlite softens and the water within the structure vaporizes, causing the material to pop (Harben 2002). Expanded perlite is then bagged for further shipping, often by truck, to nearby markets. Perlite is used in horticultural applications such as hydroponics, landscaping, and home gardening. It also helps to deter compaction in heavy-traffic areas such as golf greens and stadium turf and to maintain porosity so water will soak into the soil. Perlite is marketed for its neutral pH, its durability, and its ability to improve water retention.

Zeolites

Zeolites are hydrated aluminosilicates of volcanic origin that have an open structure, which gives them a high CEC. Zeolites can absorb and release nutrients or moisture without changing the characteristics of the minerals. Fertilizers and moisture stay accessible to the plant roots longer when they are within the zeolitic structure. They are useful in reducing the leaching of nutrients from sandy soils. Zeolites are widely used as soil amendments in Eastern Europe and Japan, but have a limited market in the United States (Hall 1998).

Diatomite

Diatomite is composed of fossilized skeletal remains of microscopic single-celled aquatic plants called diatoms, which consist of amorphous hydrous silica. Diatomite has several uses including filter aids, absorbents, and fillers. The porous skeletal structure of the diatoms have a high surface area and low bulking value, allowing them to absorb up to three times their weight while remaining free-flowing (P. Harben, personal communication). As a soil amendment these properties are exploited for water absorption and retention in turf farm and golf course applications. Zeolites are often used instead of diatomite because their superior CEC helps retain nutrients, maximizing fertilizer productivity and minimizing nutrient run-off (P. Harben, personal communication).

Silica Sand

Sand is used primarily to improve the physical properties of the soil. Although silica sand may be added to soil to improve drainage, it may have the opposite effect in heavy clay soils. The clay will tend to fill the spaces between the sand particles, acting like a cement. Coarse sand improves the drainage properties of container mixes that do not include clay soil.

Fly Ash

Fly ash is a by-product of the coal combustion process. It is the noncombustible material in the pulverized coal that is kept in suspension in the flue gas and captured by either electrostatic precipitators or mechanical means. Fly ash that is not suitable for its major use in concrete and cement has the potential for use as a soil additive. About 60% of fly ash tends to be spherical because the molten material is suspended in the flue gas (Figure 2). As a soil amendment, Class C fly ash, which contains increased amounts of

Figure 2. Secondary electron image of fly ash glass spheres and masses (field of view = 42 μ m)

calcium, can neutralize acidic soils and increase availability of nutrients (see Construction Uses: Pozzolans and Other Supplementary Cementitious Materials chapter for classification). High-calcium Class C fly ash can also control the swell potential of expansive soils and stabilize coarse-grained soils. Class F fly ash, (70% silica [SiO_2] + aluminum oxide [Al_2O_3] + iron oxide [Fe_2O_3]) aids in the compaction and soil density of poorly graded sandy soils. Water retention is increased in sandy soils by adding the small fly ash particles that fill the voids between the sand-sized grains. With silty soils, lime is required to create pozzolanic (cementitious) reactions between the clay and fly ash before adding Class F fly ash to reduce soil plasticity and improve workability. In clayey soil or a sandy soil, fly ash increases microporosity and water retention (Mitra et al. 2003). Class F fly ash can also improve soil texture because of its fineness and spherical nature. Fly ash mixed with bottom ash and blended with biosolids may be substituted for peat as a soil amendment (EPRI 2002). Fly ash does not currently have a developed market in soil amendments.

Organic Soil Amendments

Organic soil amendments are widely thought to contain humic acids that are beneficial to plants. Humic material is not a pure substance, and much confusion exists in the scientific and business communities about its terminology. *Humic acids* are defined as base-soluble humic, fulvic, and ulvic acids and their salts, formed during partial or complete decay of organic matter. This decay releases a high-molecular-weight material that is darkly colored, partly colloidal, and weakly acidic (Roybal and Barker 1986). Humic acids are organic colloids similar in behavior to clays (Siemers and Wadell 1977), increasing the water retention and CEC of the soil (Gosz, Barton, and Potter 1978). Humic acids raise the acidity of alkali soil, thus increasing the availability of several elements to plants (Siemers 1975). They also stimulate the growth of microorganisms that process plant nutrients.

Humate

Humate, when used as a lithologic term, includes oxidized coals and lignites, organic-rich mudstones and claystones, and the concentrations of humic substances often found in sandstones. Three different categories of humic materials are used to denote the different origins. Humate is commonly associated with both coal and lignite.

Figure 3. Plant facilities at the Mesa Verde Resources humate operation, San Ysidro, New Mexico (supersacks shown in foreground; milling plant behind)

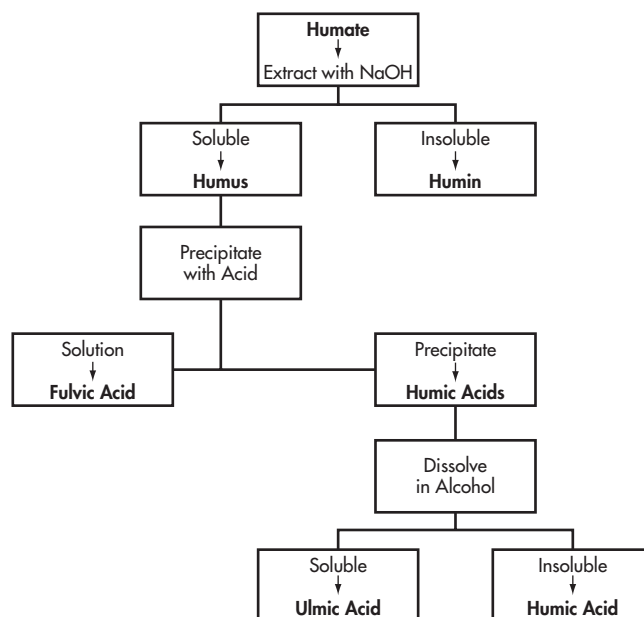

Humic material associated with oxidized lignite in the Williston Basin in North Dakota and in the Canadian provinces of Saskatchewan and Alberta has been called Leonardite, after A.G. Leonard of the North Dakota Geological Survey (Kohanowski 1970). The humic acid content of lignite decreases rapidly as coal rank increases and oxidation decreases (Abbott 1963). The third category of humates is organic-rich mudstones that are within the coal-bearing sequences. These mudstones generally have a lower humic acid content than either the oxidized lignites or coals.

Humate generally is mined by front-end loaders and stockpiled to dry before processing at the mill, where the humate is crushed and screened (Figure 3). For some uses, the material is custom blended to obtain a specific humic acid content. After the material is crushed, it is shipped in bulk, bagged, or run through an extraction process to produce a liquid. Most humate is sold to commercial farms in bulk bags or supersacks, but some of the bagged or liquid form is sold at nurseries for home gardening.

Humates are tested for the humic acid content that in part determines the product's end use. Most testing procedures include extraction of humic acid using varying concentrations of sodium hydroxide (NaOH) and different leach times in nitrogen or air atmosphere (Figure 4). Studies by Verploegh and Brandvold (1990) showed that leach solutions of 0.1 M NaOH and leach times of 1 hour are sufficient to determine the humic acid content. Reporting on humic and fulvic acids on an ash-free basis eliminates metals inherent in the humate structure (Stevenson 1985) and contaminants such as Na^+ and Cl^- . This is especially true for fulvic acids. The addition of an ashing step to the procedure and reporting on an ash-free basis would make the analyses of humate consistent by eliminating differences in results caused by varying leach times, NaOH concentrations, or both (Verploegh and Brandvold 1990).

Humate is applied to fields in the dry form at a rate of 448 to 672 kg/ha, depending on the pH of the alkali soil (Shomaker and Hiss 1974). Liquid humate may be used alone or added to other nutrients and sprayed on the soil (J.T. Spence, personal communication).

Transportation of humate in the United States is predominantly by truck, although rail is used for some shipments. Overseas shipments are generally of the liquid or bagged product. Markets

Figure 4. General analytical flowchart for determining the various components of humate

for humate from New Mexico sold as a soil additive include all the contiguous states and Hawaii, plus Central America, the Caribbean, and Taiwan (T. Taylor and B. Reid, personal communication).

The beneficial use of humate as a soil amendment has often been discounted. Several studies have not shown significant improvement in yield with humate application (e.g., McFarland, Stichler, and Lemar 2002). Humates are not beneficial for every type of soil, particularly soils already rich in clay material. The humic and fulvic acids in humates are organic colloids, similar in behavior to clay minerals that increase the water retention and CEC of the soil. Humate lowers the pH of alkaline soil, thus increasing plant nutrient availability and stimulating growth of microorganisms (Hoffman, Barker, and Austin 1995).

A perusal of Web sites and literature shows the variety of opinions on whether humate increases crop yield and whether the benefits of humate have been overstated (Hall 1998). This confusion and controversy has had a negative effect on the acceptance of humate in this market. Better evaluation of the raw products and standardized tests and specifications are needed to clear up the controversy.

Peat

Peat is also a source of partially decomposed plant material (humus). Peat, particularly sphagnum peat, helps retain water and aerate the soil. Sphagnum peat also tends to be acidic and can lower the pH of alkaline soil. Peat consists of decomposed to partially decomposed heterogeneous plant material that has accumulated in a water-saturated environment and in the absence of oxygen. Different types of peat are derived from different plant materials. Sphagnum peat moss has at least 90% organic matter on a dry-weight basis and contains a minimum of 75% sphagnum moss fiber. There are more than 355 species of sphagnum moss throughout the world; they grow in northern cool regions and are found in bogs in the northern United States and Canada (Kasica 1997). Hypnum peat moss is also found in the northern United States; it tends to break

down more quickly than sphagnum. Hypnum peat moss must contain 90% organic matter by dry weight and contain a minimum of 50% hypnum moss. Reed and sedge peat is made up of marsh plants, including reed grasses, rushes, and sedges. This material decomposes quickly, is characterized by fine particles and low fiber content, and is less acidic than sphagnum. Sedge peat contains more plant nutrients and has a higher CEC than sphagnum (Kasica 1997). Peat humus is composed of reed sedge or hypnum material but is extensively decomposed and has less than 33% peat fiber.

Peat is harvested from bogs during the warmer months of the year. The bog is drained using closely spaced ditches, and large plant debris such as trunks and limbs are cleared before peat harvesting can begin. The uppermost layer of the bog is harrowed to break capillary action and promote the drying process. After 1 to 3 days, the peat layer is collected using large vacuum harvesters (Figure 5). The peat is transported to the processing plant for drying, shredding, screening, grinding, and packaging. The drying process is by natural and/or artificial means. After drying, the peat is shredded and screened. The larger-size material is ground or put through a hammer mill and screened again. Some material is left in bulk form and blended for large applications, such as golf courses. The processed peat is blended with vermiculite, perlite, or sand for potting soil. Large bales (1.1 m^3 or 1.7 m^3) of peat are compressed to a 2:1 ratio.

ASTM has established requirements for different types of peat. The accepted value for air-dried peat is 55% moisture and <25% ash on a dry-weight basis. The minimum particle size is 0.15 mm and the maximum is 12.5 mm. The ASTM D1997 testing method for peat is based on the genetic origin and fiber content on an oven-dried basis. The resulting categories are moss peat, which includes sphagnum, hypnum, and other mosses; reed-sedge peat, the main organic constituents of which are derived from reeds or sedges or other swamp material; and humus, which is made up of decomposed material of indeterminate biological origin. Because sphagnum peats are light and fibrous and low in moisture content, they can be compressed into bales and sold by volume. Other peats tend to have a greater degree of decomposition, are higher in moisture content, and are sold by weight (Davis 1985).

The U.S. Department of Agriculture (USDA 1999b) developed another classification of peat based on the level of decomposition and resulting fiber content. Fibric peat has undergone little decomposition and contains three fourths or more (by volume) plant fibers. Hemic peat shows moderate decomposition and contains one third to two thirds (by volume) plant fibers. Sapric peat has undergone extensive decomposition and contains less than one sixth (by volume) fibers.

Another method of classifying peat used in Canada is the von Post system, which assigns grades according to the degree of decomposition or the level of humification (Troyer 1985). There are ten grades in this system, from H1 through H10. Horticultural peat, which has little or no decomposition of plant material, is in the range from H1 to H4 on the von Post scale. With greater degrees of decomposition or humification, peat loses its absorptive properties and has increased density. This peat has a higher von Post grade (H5 to H10) and is used for fuel.

Peat is tilled into clay soils to loosen the soil and added to sandy soils to retain moisture. The organic matter in peat helps to enrich depleted soils. Peat is mixed with fertilizers, vermiculite, and perlite to form a substrate. It is also mixed with limestone, soil, and fertilizers for potting soil (Prud'homme 1989). Principal commercial uses of peat are as a base for building lawns and gardens, for turf maintenance of golf courses, and for potting soil (Jasinski 2003). Peat is also used in mushroom beds and as an earthworm-culture medium.

Figure 5. Peat harvester vacuuming peat at an operation in Nova Scotia, Canada

Common uses are as a seed carrier and in the production of peat pots for sprouting plants (Prud'homme 1989).

Most peat produced in the United States is sold within a 240-km radius of the source because of the high moisture content and the resulting density (approximately 370 kg/m^3), which make it economically prohibitive to transport great distances. Because of its lower density (171 kg/m^3), sphagnum moss is baled and shipped greater distances, typically by truck (Cantrell 1991; R. Cantrell, personal communication). Generally, long distances to market are a barrier for low-cost soil amendments; however, Canadian peat is an exception. Peat imports from Canada are shipped almost anywhere in the United States because of the wide acceptance and popularity of peat as a soil amendment.

Canadian peat producers have formed a national peat association to increase sales in the United States (Prud'homme 1989), and several European countries have peat associations as well. The International Peat Society promotes scientific and technical knowledge of peat production and usage. Belarus, Russia, Ukraine, and other countries of the Commonwealth of Independent States control a large portion of the European peat market because of their large reserves and production. In many parts of the world, the major market for peat is as an energy source with secondary use as a soil amendment (Table 3). The majority of Ireland's and Finland's peat production is for fuel usage. Germany and Canada are major producers of horticultural peat.

GOVERNMENT, ENVIRONMENTAL, AND HEALTH CONSIDERATIONS

Other than simple dust problems, no environmental or health considerations are currently recognized for lime stone, dolostone, gypsum, perlite, sulfur, or humate. In the case of vermiculite, there is a question of possible association with common amphibole asbestos minerals as was the case in the deposit at Libby, Montana. This deposit, however, is no longer being mined. Vermiculite sold in the United States, produced domestically in Virginia and South Carolina or imported from South Africa, is not associated with asbestos-like minerals.

Some trace elements are concentrated in fly ash during the combustion process. There is some concern that trace elements could be leached from fly ash and could contaminate the groundwater; however, many of these elements have very low solubility in the ash (glass) matrix (D. Pflughoeft-Hassett, personal communication). The

† Estimated.

permitting of new bogs for peat harvesting is a growing problem because they overlap with wetland areas. The cost of compliance and permitting new peat bogs is eliminating small operators. The Canadian Sphagnum Peat Moss Association is working with the North American Wetlands Conservation Council on conservation and restoration projects (Daigle and Gautreau-Daigle 2001).

TRENDS AND OPPORTUNITIES

The trend toward sustainable development is increasing the need to use by-products instead of nonrenewable materials. As an example, the increased use of synthetic gypsum from FGD could result in less use of natural gypsum. In addition, recycled gypsum or ground scrap wallboard can be used for agricultural uses. Slag from iron and steel processes could capture some of the agricultural additive markets, particularly in the eastern United States. The horticultural market in Canada is growing, as is the export market for U.S. perlite, as imports of perlite from Greece are taking over part of the market along the east coast of the United States.

ACKNOWLEDGMENTS

The authors thank Bruce Harrison for his careful review of this chapter, and Peter W. Harben for his review and additions. Both reviewers greatly improved the accuracy and content.

Well Drilling Materials

Syed A. Ali and William E. Foxenberg

INTRODUCTION

Drilling fluids—or *muds* as they are commonly called—play a crucial role in the drilling of oil and gas wells. These fluids are formulated to perform a variety of functions under a wide range of downhole temperatures, pressures, and lithologies. The drilling fluid is pumped down the hollow drill string through nozzles in the drill bit at the bottom of the well, then up through the annulus (which is formed by the drill string and the wellbore), removing formation material dislodged by the drill bit. The drill bit is turned by rotating the entire drill string or by using a downhole motor to rotate the drill bit. After reaching the surface, drilling fluid passes through a series of vibrating screens, settling tanks/pits, and hydrocyclones to remove suspended formation material. The drilling fluid is then treated to maintain the desired physical and chemical properties. Once treated, the drilling fluid is pumped back into the well and the process is repeated.

Drilling fluids comprise liquids (water, petroleum oils, and other organic liquids), dissolved inorganic and organic additives, and properly sized suspended solids of various types. The chemistry of the liquid phase dictates the type and amount of materials needed to maintain the required density, viscosity, and other rheological properties. The drilling fluids must have sufficient density to offset formation pressures, prevent blowouts, and maintain a stable wellbore. They must be formulated to prevent damage to permeable formations by controlling excessive fluid loss. Other functions of drilling fluids include lubrication of the drill bit and drill string, prevention of corrosion, and collection of subsurface information through well logging.

A number of industrial minerals, chemicals, and other materials are used as additives in the drilling fluid to accomplish the aforementioned functions. Industrial minerals such as barite and bentonite make up the largest percentage of the additives in a drilling fluid. Other minerals such as gypsum, limestone, and attapulgite make up a small percentage of total demand.

INDUSTRIAL USES OF MATERIALS

Industrial minerals in drilling fluids have seven basic uses: weighting agents, bridging agents, viscosifiers, thinners, lost-circulation materials, stabilizers, lubricants, and proppants and plugs.

Weighting Agents

Barite, hematite, and galena are weighting agents with high specific gravities; they help offset pressure, control liquid flow into

the wellbore from the formation, and keep the hole open. Galena is used only in preparing extremely heavy muds that are sometimes needed to control abnormally high pressures; it is not a common component of weighted muds. A supply of galena is maintained in the U.S. Gulf Coast area for emergency use. Barite is the most common weighting material for heavy muds, followed by hematite. Siderite and limestone (calcium carbonate) are often used for low-density muds and for workover/completion fluids because they are acid soluble.

Bridging Agents

Sized calcium carbonate and sized salt are commonly used as bridging agents in drill-in fluids. The drill-in fluids enable horizontal wells to be completed without formation damage caused by conventional drilling fluids. Drill-in fluids are classified as either solids free or minimal solids systems. The solids content is limited to bridging agents, which plug the pore spaces at the wellbore face, thereby restricting the invasion of solids and fluids into the formation. The bridging agents are sized to formation properties (i.e., pore geometry) and comprise either calcium carbonate or salt crystals.

Viscosifiers

Sodium bentonite and peptized calcium bentonite are the most common viscosifiers for freshwater muds, whereas attapulgite and sepiolite are the most common for saltwater muds. The organophilic clays are used as viscosifiers in oil muds. A viscosifier carries the cuttings to the surface, builds a cake against permeable formations, and lubricates the drill string.

Thinners

Thinners are added to mud to obtain better flow properties. Materials commonly used as thinners can be broadly classified as (1) plant tannins, (2) polyphosphates, (3) leonardite, (4) specialty products derived from leonardite, and (5) lignosulfonates. Thinners are often referred to as *mud-conditioning agents*.

Lost-Circulation Materials

Gilsonite, mica, diatomaceous earth, and expanded perlite and vermiculite are used to plug or seal pores and cracks in the formation being drilled. Mica is the most common industrial mineral used to reduce lost circulation. The bentonites and organophilic clays also help with lost-circulation problems.

Stabilizers

Gilsonite and salt stabilize a wellbore when drilling through shale or salt formations. Gypsum is used as a stabilizer when drilling anhydrite or gypsum. Adding salt or gypsum prevents the drilling fluid from dissolving the salt, gypsum, or anhydrite in the formation being drilled; Gilsonite coats shales, which prevents them from absorbing water, expanding, and subsequently caving into the wellbore.

Lubricants

Graphite and bentonite lubricate the drill bit and drill pipe during a drilling operation. They also help prevent the pipe joints from sticking.

Proppants

Sized silica sand is used as a propping agent for fracturing, a process that holds the fractures open and enables the oil to flow out of the formation into the well. Sized silica sand is also used in gravel packing of poorly consolidated sands.

Plugs

Aggregate and granular-size bentonite is currently used for plugging shallow seismic holes. The completed holes are filled with this material to prevent inflow of water. Highly compressed sodium bentonite is also used for well abandonment.

Specialty Products

Attapulgit, sodium bentonite, and calcium bentonite are used to make organophilic clays. Organophilic clays are used in oil-based muds as viscosifiers and filtrate reducers. A series of specialty products are generated from leonardite through caustic treatment, sulfonation, sulfomethylation, or chelation with zinc. Attapulgit, sodium bentonite, calcium bentonite, and leonardite make up more than 50% of specialty products. The products are proprietary. Other industrial minerals are used in these specialty products in very small amounts as fillers.

INDUSTRIAL MINERALS

Table 1 lists the industrial minerals commonly used in drilling fluids, and their forms, specifications, and uses. In this section each mineral is discussed as to its mineralogy, physical and chemical properties, and the location of major deposits. More detailed information may also be found in individual chapters in this volume covering each of these mineral commodities.

Asbestos

Although no longer used in drilling fluids, at one time asbestos was commonly added to water-based muds as a highly effective viscosifier.

Asbestos is the generic name for a group of naturally occurring fibrous silicate minerals. The principal component of commercial asbestos is chrysotile (hydrated magnesium silicate). Chrysotile has a specific gravity of 2.55 and a Mohs hardness of 2.5. It consists of tubular, parallel fibers that are closely packed. The fibrous nature of chrysotile leads to the development of a brush-heap structure when it is dispersed in either salt water or freshwater. The major asbestos deposits are located in the province of Quebec, Canada, and near Coalinga, California.

Attapulgit (Palygorskite)

Attapulgit is a crystalline hydrated magnesium silicate, with partial replacement of magnesium by aluminum, iron, and other elements. Attapulgit particles are needlelike in shape. When placed in

water, attapulgit does not swell like bentonite but must be dispersed by vigorous stirring to break up the bundles of lath-like crystals. Attapulgit is used in drilling fluids solely for its suspending properties, which are not affected by dissolved salts. In fact, attapulgit generates a higher viscosity in saturated sodium chloride solution than in freshwater. Attapulgit has a specific gravity of 2.5 and a Mohs hardness of 1 to 1.5. Attapulgit, often referred to as *fuller's earth*, is also used to produce organophilic clay.

The major producing areas in the United States are in southern Georgia and north western Florida. It is also mined in Australia, India, Senegal, South Africa, and Spain.

Barite

Pure barite (BaSO_4) has a specific gravity of 4.5 and a Mohs hardness of 2.5 to 3.5. Commercial barite often exhibits a lower specific gravity because of impurities such as quartz, chert, gypsum, anhydrite, celestite, and various iron minerals. The presence of iron minerals may, however, increase the specific gravity of commercial barite. Barite is used primarily as a weighting agent in drilling fluids.

Pure barite does not react with other components of drilling fluids and is virtually insoluble in water, but impurities in barite can influence drilling-fluid properties. For example, calcium sulfate minerals (i.e., gypsum and anhydrite) may thicken drilling mud. Likewise, properties of drilling mud may be adversely affected by the presence of sulfide minerals (i.e., pyrite and sphalerite), which can undergo oxidation, forming soluble salts.

The United States is a major producer and by far the leading consumer of barite. The oil industry uses 90% of domestic production and almost all the imported barite. Major producing states are Georgia and Nevada. The principal sources of imported barite are China, India, and Morocco.

Bentonite

Bentonite is primarily composed of the clay mineral montmorillonite, a magnesium–aluminum silicate. Bentonite hydrates in freshwater and disperses to varying degrees, depending on the nature of the cations that are loosely held and exchangeable (high cation exchange capacity). The presence of exchangeable sodium ions enhances hydration and dispersion. Divalent cations such as calcium reduce the degree to which the individual platelets disperse. Bentonite is added to freshwater muds for one or more of the following purposes: (1) to increase the borehole cleaning capability; (2) to reduce filtration into the permeable formations; (3) to form a thin, low permeability filter cake; (4) to promote borehole stability in poorly consolidated formations; and (5) to control loss of circulation. Bentonite has a specific gravity of 2.5 and a Mohs hardness of 1 to 1.5. It ranks second in quantity only to barite as a drilling-fluid additive. Bentonite is also used to produce organophilic clays. Calcium bentonite is often treated with sodium carbonate and polyacrylates to meet American Petroleum Institute (API) specifications.

Bentonite, in which sodium naturally predominates as the exchangeable cation, is mined primarily in Montana, South Dakota, and Wyoming. Arizona, California, Nevada, Oregon, and Utah also supply sodium bentonite. Production of calcium bentonite occurs in Alabama, Arizona, California, Colorado, Mississippi, Nevada, Oregon, and Texas. Major deposits outside the United States are in Argentina, Brazil, Cyprus, Germany, Greece, India, Italy, Mexico, and Turkey.

Diatomite (Diatomaceous Earth)

Diatomite, or diatomaceous earth, is composed primarily of diatom skeletons (hydrous silica). It has a limited use in drilling fluid as a fluid-loss control agent. Diatomite is primarily used as a filter

Table 1. Industrial minerals used in well drilling

Additives	Form	Specifications	Use
Asbestos	Fibrous	None	No longer used either as a viscosifier or lost-circulation material because it is classified as a carcinogen
Attapulgitite*	Powder—75 µm	30-min reading on a motor-driven, direct indicating viscometer at 600 rpm with a mixture of 20.0 g material in 350 cm ³ saturated salt solution; residue >75 µm: 8% max.; moisture: 16% max.	Viscosifier in saltwater
Barite*	Powder—75 µm	Density: 4.20 g/cm ³ min.; water-soluble alkaline earth metals as calcium: 250 mg/kg max.; residue >75 µm: 3% max.; particles <6 µm: 30% max.	Weighting agent
Bentonite (sodium)*	Powder—75 µm	30-min reading on a motor-driven, direct indicating viscometer at 600 rpm with a mixture of 22.5 g material in 350 cm ³ distilled water; yield point/plastic viscosity ratio: 3 max.; filtrate: 15 cm ³ max; residue >75 µm: 4% max.; moisture: 10% max.	Viscosifier in freshwater
Nontreated bentonite*	Powder—75 µm	30-min reading on a motor-driven, direct indicating viscometer at 600 rpm with a mixture of 25.0 g material in 350 cm ³ distilled water; yield point/plastic viscosity ratio: 1.5 max.; dispersed plastic; viscosity: 10 Cp min.; filtrate: 12.5 cm ³ max.	Viscosifier in freshwater
OCMA-grade bentonite (calcium)†	Powder—75 µm	30-min reading on a motor-driven, direct indicating viscometer at 600 rpm with a mixture of 22.5 g material in 350 cm ³ distilled water; yield point/plastic viscosity ratio: 6 max.; filtrate: 16 cm ³ max.; residue >75 µm: 2.5% max.; moisture: 13% max.	Viscosifier in freshwater
Diatomaceous earth	Powder	None	Lost-circulation material
Galena	Powder	None	Weighting agent
Gilsonite	Powder	None	Stabilizer
Graphite	Powder	None	Lubricant
Gypsum	Powder	None	Stabilizer
Hematite*	Powder—75 µm	Density: 5.05 g/cm ³ min. water-soluble alkaline earths metal as calcium: 100 mg/kg max.; residue >75 µm: 1.5% max.; residue >45 µm: 15% max.; particles <6 µm: 15% max.	Weighting agent
Ilmenite	Powder	None	Weighting agent
Itabirite	Powder	None	Weighting agent
Leonardite	Powder	None	Thinner
Limestone	Powder	None	Low-density weighting agent
Mica	Flake	None	Lost-circulation material
Perlite	Powder	None	Lost-circulation material
Quartz sand	Sand	Various mesh sizes	Propping agent; gravel-packing sand
Salt	Granular	None	Stabilizer; weighting/bridging agent
Sepiolite*	Powder—75 µm	30-min reading on a motor-driven, direct indicating viscometer at 600 rpm reading 20 g material in 350 cm ³ saturated salt solution; residue >75 µm: 8% max.; moisture: 16% max.	Viscosifier in saltwater
Siderite	Powder	None	Low-density weighting agent
Soda ash	Powder	None	Remove calcium salts
Ulexite	Powder	None	Cross-linking agent
Vermiculite	Flake	None	Lost-circulation material

* American Petroleum Institute (API) specifications (Spec. 13A; API 1993).

† OCMA = Oil Companies Materials Association.

medium for completion brines. It has a specific gravity of 1.95 and a Mohs hardness of 4 to 4.5. The major deposits in the United States are in California and Nevada. Other notable producers are China, France, Italy, Japan, and Mexico.

Galena

Galena (PbS), with a specific gravity of 7.4 to 7.7 and a Mohs hardness of 2.5, is used only in preparing extremely heavy muds,

which often are required to control abnormally high pressures. Since galena is expensive, it is not a normal component of weighted muds. It is used only in emergency situations requiring weights up to 32 lb/gal. The largest galena deposits in the United States are located in Missouri, with minor production from Alaska, Idaho, and Montana. Outside the United States, the major deposits are in Australia, Canada, China, Kazakhstan, Mexico, and Peru.

Gilsonite

Gilsonite is a naturally occurring, solid carbonaceous material that is classified as an asphaltite. It is a pure hydrocarbon without any significant amounts of mineral impurities. Gilsonite has a low specific gravity and a softening point of approximately 370°F (188°C). It is used to control fluid loss, stabilize sloughing shales, and reduce borehole erosion. Major deposits of Gilsonite are found in northeastern Utah.

Graphite

Graphite is a naturally occurring carbon. It has a specific gravity of 2.3 and a Mohs hardness of 1 to 2. It is occasionally used in drilling fluids as a lubricant. Graphite is not currently mined in the United States. The major deposits are in Brazil, China, the Czech Republic, India, Madagascar, Mexico, and Sri Lanka.

Gypsum

Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) has a specific gravity of 2.32 and a Mohs hardness of 2. It is a primary source of calcium ions in "gyp" muds. The gyp muds are used for drilling sloughing shales and anhydrite formations. Nondrilling uses, however, account for most gypsum consumption. Major producing states are California, Indiana, Iowa, Michigan, Nevada, Oklahoma, and Texas. The largest producers of gypsum outside the United States are Canada, China, Iran, Japan, Mexico, Spain, and Thailand.

Halite

Halite (NaCl), or rock salt, has a specific gravity of 2.16 and a Mohs hardness of 2.5. Halite is used in formulating salt-saturated muds that are used for drilling in salt sequences, and for shale inhibition. Sized salt is often used as a water-soluble bridging agent for sealing porous formations. Recently, the use of sized salt has increased as a main component of salt-based drill-in fluid for horizontal wells.

Major salt deposits in the United States are in Louisiana, Michigan, New York, Ohio, and Utah. Outside the United States, other major deposits are found in Canada, China, and Germany.

Hematite

Hematite (Fe_2O_3) has a specific gravity of 5 to 5.26 and a Mohs hardness of 5.5 to 6. In the early 1980s, an anticipated worldwide barite shortage led to the use of hematite as a weighting agent in drilling fluids. Then it was discovered that hematite tended to increase filtrate loss and filter cake thickness. This problem, coupled with complaints from rig personnel of serious skin and clothing discoloration, caused a decline in the use of hematite as a weighting agent. In addition, hematite is more abrasive to drill bits, drill strings, and pump parts than is barite.

Hematite is mined in the Lake Superior and Appalachian Mountain regions of the United States. Outside the United States, major producing countries are Australia, Brazil, and China.

Ilmenite

Ilmenite (FeTiO_3) has a specific gravity 4.5 to 5.1 and a Mohs hardness of 5 to 6. The heavy metal content of ilmenite is lower than barite. In addition, the bioavailability of the heavy metals is lower. Environmentally, it is more desirable to use ilmenite than barite as a weighting agent in drilling fluids. Recently, a field trial was conducted using ilmenite as a weighting agent in the mud system on the Norne Field in Norway. It clearly demonstrated that the performance of ilmenite was comparable to barite. Supplies of ilmenite are abundant.

Itabirite

Itabirite is a micaceous hematite. It is called micaceous because it splits easily into thin, flat flakes, making it easily friable. It has a specific gravity of 5.1 and a Mohs hardness of 5 to 6. Abrasion is minimized if a maximum particle size of 45 μm is specified. This limiting of particle size has an additional advantage in that 120- or 150-mesh screens can be used on the shakers without excessive loss of itabirite. It can be used as weighting agent in both oil-based and water-based muds. Itabirite has successfully been used in Latin America. Brazil is a major source of itabirite.

Leonardite (Lignite)

Leonardite is naturally oxidized lignite, resulting from prolonged weathering. Leonardite is used in drilling fluids as a thinner and a filtration control agent. The name *leonardite* applies to the lignite oxidation product containing a high humic acid content. It has greater temperature stability than other thinning agents. Leonardite is a versatile material for emulsion stabilization. A derivatized version of leonardite is used in oil-based muds to reduce filtration loss and to improve the stability of water-in-oil emulsions.

North Dakota is the principal source of leonardite for drilling use. Minor deposits are located in South Dakota, Montana, New Mexico, and Texas.

Limestone (Calcium Carbonate)

Limestone, or calcium carbonate (CaCO_3), has a specific gravity of 2.7 and a Mohs hardness of 3. Calcium carbonate is often used as a weighting material because the resulting filter cake can be removed easily by treatment with hydrochloric acid. Calcium carbonate disperses more readily in oil muds than does barite. The low specific gravity of limestone limits the maximum density of the mud to about 12 lb/gal. Calcium carbonate is readily available as ground marble or oyster shells. Calcium carbonate is available in fine, medium, and coarse grades. It is used primarily as a bridging agent in both oil- and water-based drill-in fluids. Limestone deposits are ubiquitous and are mined throughout the United States and the rest of the world.

Magnetite

Magnetite (Fe_3O_4) has a specific gravity of 5.0 to 5.2 and a Mohs hardness of 5.5 to 6.5. Magnetite is no longer used as a weighting material in drilling fluids because of its relatively higher abrasiveness to drill-bit, drill-string, and pump parts. Because it is magnetic, it also causes interference with electrical logging and causes flow lines to clog.

Mica

Muscovite ($\text{KAl}_2(\text{AlSi}_3\text{O}_{10})(\text{OH})_2$) is the preferred mica mineral in drilling fluids. It has a specific gravity of 2.76 to 3.1 and a Mohs hardness of 2 to 2.5. Muscovite is flexible and insoluble in acids. It is primarily used to control loss circulation. The major deposits in the United States are in Georgia, New Mexico, North and South Carolina, and South Dakota. Outside the United States, the major deposits are in Brazil, Canada, France, and India.

Perlite

Perlite is a hydrated volcanic glass that expands greatly when heated. Expanded perlite is used for controlling loss of circulation. The largest deposits in the United States are in northern New Mexico. Outside the United States, Greece has major deposits.

Pyrite

Although pyrite (FeS_2) is not used in drilling mud, an iron-oxide weighting material is made from the residue of the pyrite roasting

process. The residue is quenched, neutralized, leached, washed, and dried. The product is milled to desired particle-size distribution. Desirable characteristics claimed for the product are high specific gravity of 4.7; low abrasion and low magnetic susceptibility; 85% solubility in hydrochloric acid; and reaction with H_2S to form polysulfides. Supplies of pyrite are abundant.

Quartz Sand

Quartz sand (SiO_2) has a specific gravity of 2.7 and a Mohs hardness of 7. Only high-quality, clean, properly sized sand is used as a proppant in fracturing of oil and gas for permeability enhancement. It is also used in gravel packing of poorly consolidated sands. The largest production of quartz sand in the United States is in Illinois, followed by Michigan, California, North Carolina, Texas, Wisconsin, New Jersey, and Oklahoma. Large deposits of high-silica industrial sand are widespread throughout the world.

Sepiolite (Meerschaum)

Sepiolite, or meerschaum, is a hydrated magnesium silicate that contains less substituted aluminum than does attapulgite, which it closely resembles. The crystal structure of sepiolite also is similar to that of attapulgite; the unit cell of sepiolite, however, is somewhat larger. Sepiolite occurs in fibrous, elongated lath-like particles. It has a specific gravity of 1 to 2 and a Mohs hardness of 2 to 2.5. It is used as a viscosifier for saltwater muds. The reported stability of sepiolite at elevated temperatures led to its application in geothermal drilling. Among the cited applications are (1) as a replacement for attapulgite in saltwater muds, (2) as a replacement for asbestos in "sweep" slugs for hole cleaning, and (3) as a packer mud. Although some sepiolite is produced in southern Nevada, Spain is the largest producer. Major deposits of sepiolite also occur in Somalia and Turkey.

Siderite

Siderite is a ferrous carbonate ($FeCO_3$). It has a specific gravity of 3.7 to 3.9 and a Mohs hardness of 3.5 to 4. It is highly soluble in acids. Siderite can be used as a weighting agent in both oil- and water-based muds. Its higher density enables the formulation of muds weighted up to 19 lb/gal. In laboratory core tests, muds containing siderite did not cause permanent damage by particulate invasion. Present domestic production of siderite is from east Texas.

Soda Ash

Soda ash is a sodium carbonate (Na_2CO_3). It has a specific gravity of 3.23 and a Mohs hardness of 3. Soda ash is used primarily to remove calcium salts from make-up waters and muds. It is also used in clay beneficiation. It is produced from either brines or trona deposits. The largest production is from trona deposits in southwestern Wyoming with additional production in California and Colorado. Botswana, Kenya, Mexico, and Turkey are the major producers outside the United States.

Ulexite

Ulexite is a hydrous sodium calcium borate ($NaCaB_5O_9 \cdot 8H_2O$). It has a specific gravity of 1.6 to 1.9 and a Mohs hardness of 2.5. It is used primarily as a source of borate for cross-linking hydrated guar gum. Cross-linked guar is used as a fracturing fluid. The largest deposits of ulexite are in Boron, California.

Vermiculite

Vermiculite is a micaceous mineral that expands when heated. The expanded form of vermiculite is used for controlling loss of circulation. The principal sources of vermiculite in the United States are

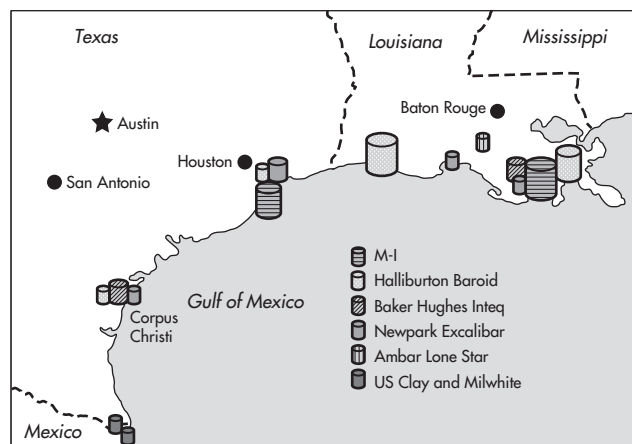

Figure 1. Plants that grind barite for drilling fluids located along the Louisiana-Texas Gulf Coast

South Carolina and Virginia. Elsewhere, the largest deposits are in South Africa.

SUPPLIERS

The industrial minerals used in drilling fluids in major amounts are barite, sodium bentonite, hematite, attapulgite, leonardite, and mica. Except for silica sand, which is used as a propping agent, the other industrial minerals are used in only minor amounts.

Drilling-fluid companies generally move the materials used in drilling fluids directly to the well site. These companies maintain warehouses and stockpoints in the major drilling areas throughout the world. If requested, they also supply drilling-fluid technologists (mud engineers), who supervise the mixing and use of the drilling mud.

There are three major worldwide drilling-fluids companies: M-I SWACO, a Smith/Schlumberger company; Baroid Drilling Fluids, a Halliburton company; and Baker Hughes Drilling Fluids, a Baker Hughes company. Additionally, there are numerous smaller, regional companies throughout the United States and worldwide. Drilling-fluid companies mine and grind the major products, or purchase them from other producers.

In the United States today, 13 plants along the Louisiana-Texas Gulf Coast (Figure 1) grind barite for drilling fluids. In addition, two other grinding plants in the same region custom grind barite for drilling-fluid companies or provide their own ground barite.

Three major mud companies own 8 of the 15 plants. The plants along the Gulf Coast supply 85% of the drilling mud barite in the United States.

In the West, three plants operate near Battle Mountain, Nevada, the largest barite mining area in the United States, and one operates near Salt Lake City. The ground product from these areas supplies the western United States and Alaska. Additionally, two other plants, one in Oklahoma and another in West Texas, grind barite for the drilling-mud market.

Other plants throughout the United States grind barite for the drilling-mud market, but their primary business is other minerals or the filler-grade barite market. In addition to the operating plants, several plants have been mothballed since the downturn in the market in 1982.

Sodium bentonite is the second largest industrial mineral used in drilling fluids based on tonnage. Five companies with 12 operating

plants produce drilling-grade products: American Colloid; Bentonite Corporation (formerly part of Baroid); Black Hills Bentonite; M-I SWACO; and WYO-BEN Corporation. Eleven of the plants are in Wyoming: five are in the Big Horn Basin in northwestern Wyoming, two are in the Casper area, and four are in the northeastern part of the state. The twelfth plant is in the northwestern corner of South Dakota. The plants produce ground and granular bentonite for domestic and foreign markets, and crushed and dried bentonite for export to grinding plants in other major drilling-mud markets in the world.

M-I SWACO and Densimix import specularite hematite from Brazil for the drilling-fluid market. Two plants on the Gulf Coast screen, dry, and, if necessary, grind the filter cake. These companies supply the other drilling-fluid companies with most of the product that they require.

Four companies produce attapulgite in the Georgia-Florida area as a ground product for the drilling-mud market and other uses. The four companies are Engelhard Mineral and Chemical Company; Floridin Company; Oil-Dri Corporation of America; and the Milwhite Company. The products are packaged in bags bearing the names of the drilling-fluid companies. Attapulgite-sepiolite is also ground and packed in Spain and Senegal.

Leonardite is produced in southwestern North Dakota and near Glenrock, Wyoming, for the drilling-fluids market. The three major suppliers are Black Hills Bentonite in Wyoming and American Colloid and Geo Resources in North Dakota. The material is supplied in powder form and packed and labeled in multiwalled paper bags from either the producer or the customer. The producers also sell leonardite in crushed and dried lumps for further processing.

Mica is supplied to the drilling-mud industry in ground form. The two major producers for the drilling-mud market are KMG Minerals in North Carolina and Mineral Mining Corporation in South Carolina. Most of the material is a flotation product or from scrap. The producers package the ground or screened product in paper bags with the customer's trade name. Canada and India supply mica to the drilling-mud industry in some international markets.

Other minerals used in minor amounts in drilling are obtained from suppliers either in generic bags or with the customer's name. These minerals are only a very small portion of the producers' total output.

TECHNOLOGY

Processing barite involves a rotary breaker that uses water at high pressure to separate the softer barite from the harder gangue, which is discarded. The barite and the remaining gangue move on to log washers, where any clay is separated. A trammel screen is used to discard oversize gravel material. The remaining material containing barite then moves on to jigs for the final gravity separation of barite from the remaining fine gravel gangue. The barite is then dried, ground, and packed in multiwalled paper bags.

For attapulgite, bentonite, sepiolite, and leonardite, all the raw materials used to produce the finished products are crushed, dried, ground, and packed in multiwalled paper bags. Before this processing, the clays and leonardite are dried either at the mine or on the stockpiles at the plant. This decreases the amount of water that must be removed in drying and makes the material easier to crush. Rotary dryers dry the clays at relatively low temperatures. If too-high temperatures are used, molecular and spatial water is driven off, and the swelling capability of the clays is decreased.

Table 1 lists specifications for the three grades of drilling-fluid bentonite recognized by API. The higher performance grades are produced mainly in Montana, South Dakota, and Wyoming. This bentonite contains montmorillonite clay in both sodium and cal-

cium forms; the sodium form, however, predominates. Most of these bentonites are processed using a small amount of a peptizing polymer to enhance the viscosity-building properties of the clay. This peptized bentonite is referred to as the standard API bentonite. The high-quality bentonite that is not treated in any way to enhance its viscosity-building characteristics is designated and sold as API nontreated bentonite.

Large deposits of calcium bentonite found in the coastal plains of the Gulf of Mexico and many other areas around the world are low-yielding bentonites. These can be used in drilling muds if upgraded with sodium carbonates and peptizing polymers such as polyacrylates. The name API OCMA bentonite identifies such bentonites for drilling use. "OCMA" refers to the defunct organization Oil Companies Materials Association, which set specifications until the early 1980s for drilling-fluid materials used outside the United States. The API, which has adopted and upgraded many of the old OCMA specifications, is the organization that today determines and sets such specifications.

Fast-yielding bentonites, when treated with high-molecular-weight polyacrylamide and polyacrylates, produce roughly the same viscosity as twice the amount of untreated bentonite. These polymers are referred to as bentonite extenders. Another bentonite extender is a mixed metal (magnesium and aluminum) layered hydroxide, or MMH. A MMH is most frequently used to increase viscosity sufficiently so that metal cuttings can be removed from the well during the milling operation. MMH-treated muds also are finding applications in horizontal wells. Unfortunately, when bentonites are treated in this manner, it can decrease the shelf life of the product and may increase fluid loss beyond specifications. This is especially true for calcium bentonites.

It is not uncommon to treat attapulgite with magnesium oxide and magnesium hydroxide to increase its mud-thickening ability. The effect can be heightened by including mannogalactan from guar.

Organophilic clay supplies viscosity and suspending qualities in oil-based muds. It is prepared from bentonite or attapulgite and aliphatic amine salts. The organophilic clays obtained from amines having 12 or more straight-chain carbon atoms that swell and form gels in oils. The amino groups replace the sodium and calcium originally present on the clay surface. Organophilic clays can suspend solids in oil without requiring additional emulsifying surfactants.

Processing leonardite involves moving the soft, moist deposit to stockpiles, where some drying and possibly some oxidation occur. This material is then passed through a low-temperature dryer to reduce the moisture content to 15%–20%. The dried product is then crushed and bagged. The performance of leonardite can be greatly improved by solubilizing processes such as caustic treatment, sulfonation, sulfomethylation, or chelation with heavy metals.

Specular hematite is mined and partially processed in Brazil before shipment as filter cake to the United States, where the final processing steps are performed. A small amount of agglomerated material may have formed, and some tramp material may have been picked up during transportation and storage. Because of these possibilities and the 8% to 10% moisture content, the material is dried either in a rotary dryer or a flash dryer (on the mill) and screened before packing. A hammer mill or a ring-roller mill breaks up the agglomerates.

Mica for drilling-mud products is dry-ground flake mica. It is ground further and screened to the sizes required for drilling mud use.

All these products are packaged in multiwalled paper bags and/or plastic 1-t supersacks. Barite and hematite are also delivered in bulk.

Specifications

Table 1 gives specifications for industrial minerals used in well drilling. API publishes specifications for barite, bentonite (sodium), hematite, nontreated bentonite (sodium), OCMA bentonite (calcium), attapulgite, and sepiolite (API 1993). These specifications are revised periodically. A few users set additional specifications for some products. For barite, the amount of caustic soluble material is usually limited to 3,000 mg/L for carbonates and 50 mg/L for sulfides. The amount an API bentonite can be extended with polyacrylates and still have an acceptable yield point is limited to 1.81 kg/t of polyacrylate and a minimum yield point of 60. Drilling-fluid companies usually set the specifications for the other minerals. Additionally, U.S. Environmental Protection Agency (EPA) and also some state agencies in the United States have set limits for heavy metal content (i.e., their use and disposal) in barite, muds, and cuttings.

Testing

The API has set standard test procedures along with specifications for the industrial minerals used in drilling fluids. In addition, API also has a recommended practice for chemical analysis of barite (API 1996). The EPA has standard test procedures for measuring mercury and cadmium. Most drilling-fluid companies have their own test methods for materials other than those specified by API. Some states require certification of processing facilities by NSF International for products used in water-well drilling.

ECONOMIC FACTORS

Costs

The largest industrial use of barite and bentonite is in well drilling. The other industrial minerals used in well drilling comprise only a small portion of the total tonnages produced each year. The major cost items to produce barite, bentonite, and most other industrial minerals are mining, grinding, and packaging. Mining must be economical; therefore, surface mining is usually practiced. Generally, it is prohibitive to concentrate barite for the drilling-mud market by any means other than screening, washing, or jigging. Dry grinding with ring-roller mills is more economical than grinding with ball mills.

Packaging is becoming more automated with palletizers to reduce labor costs. Other costs that continue to increase are those related to quality control, environmental considerations, and reclamation.

Markets

Most of the well-drilling outlay in the United States and worldwide is for oil and gas. The API sets the specifications for the major additives used in the drilling industry. If a company wishes to use the API logo on its products, it must have an API-approved Q-I program (quality control).

The largest single market area for drilling muds in the United States is the Louisiana–Texas Gulf Coast. Fifteen barite grinding plants on the Gulf Coast supply this market. The other major market areas for drilling muds are California and Alaska, the Rocky Mountains, and the midcontinent region (Kansas, New Mexico, Oklahoma, and Texas). Drilling-fluid companies maintain warehouses to supply their customers in these areas.

Transportation

Most of the industrial minerals used in well drilling have unique physical properties and are found in only a few areas. Materials of restricted occurrence that are shipped long distances, such as sodium bentonite, leonardite, and attapulgite, usually are shipped by rail in carload lots.

Lump barite and specularite hematite are mostly imported. The volume of sea freight of barite from the foreign producing countries in bulk quantities is less than the volume of rail freight from Nevada to the U.S. Gulf Coast, the largest consuming area.

GOVERNMENTAL CONSIDERATIONS

Taxes and Depletion

Most states have severance or ad valorem taxes on the industrial minerals used in well drilling. The trend is for increases in the taxes. Depletion allowances apply to all the industrial minerals used in well drilling. Import taxes are collected on most of the industrial minerals used in well drilling. The rates are different and depend on the source country, and whether it has Normal Trade Relations status; for a developing country, the imports are duty free.

Land Use

All mining operations in the United States must now reclaim mined areas whether on private or public lands. Usually an equivalent area must be reclaimed for the area mined each year. Each state has slightly different regulations.

Environmental Regulations

In 1988, EPA proposed a limit of 1 mg/kg mercury and 1 mg/kg cadmium in barite. The industry argued that the availability of barite at the proposed concentrations was limited and that the limit would increase the cost of barite by 65%. Industry-supplied data indicated that adequate supplies of barite containing <3 mg/kg mercury and 5 mg/kg cadmium were available. In 1993, EPA proposed a new regulation based on barite containing a maximum of 3 mg/kg mercury and 5 mg/kg cadmium. The use of barite would not be regulated, but the discharge of the mud and the cuttings would be monitored and regulated. Louisiana has some limits on heavy metals contained in the mud stored in mud pits. Current EPA permits for discharge require limits of 1 mg/kg mercury and 3 mg/kg cadmium.

In the United States there are regulations on rainwater runoff from mines and processing plants, acid mine drainage, and dust emissions.

Safety Regulations

Mines, concentrating plants, and grinding plants in the United States are regulated under the Mine Safety and Health Act of 1977.

PROBLEMS AND FUTURE TRENDS

The trend in the United States is to import oil rather than produce it because of the economics of drilling in the United States versus drilling elsewhere. This trend will reduce the amount of industrial minerals used in domestic well drilling. Increased governmental regulations on the environment, land use and land withdrawals, and increases in severance and ad valorem taxes all increase the cost of production, thus reducing the competitiveness of the United States. China has become the largest supplier of barite and is increasingly producing large quantities of other oilfield minerals and chemicals.

Resource and Reserve Classification

Unless stated otherwise, reference to *reserves* and *resources* in this volume follows the terminology promulgated by SME's *Guide for Reporting Exploration Information, Mineral Resources, and Mineral Reserves*, a report submitted by the Resources and Reserves Committee to the Board of Directors of the Society for Mining, Metallurgy, and Exploration, Inc., dated March 1, 1999. The terminology is shown in Figure 1 and described as follows.

Public reports of *exploration information* relating to mineralization (but not classified as a mineral resource or mineral reserve) must contain sufficient information to allow a considered and balanced judgment of the significance of the results. This must include relevant information such as the geological setting, sampling intervals and methods, sample locations, assay data, laboratory analyses, data aggregation methods, plus other information that is material to an assessment. The reporting of exploration sampling or geophysical results must not be presented so as to unreasonably imply that a potentially economic deposit has been discovered.

A *mineral resource* is a concentration or occurrence of material of intrinsic economic interest in or on the earth's crust (a *deposit*) in such form and quantity that there are reasonable prospects for eventual economic extraction. The location, quantity, grade, geological characteristics, and continuity of a mineral resource are known, estimated, or interpreted from specific geological evidence and knowledge. Mineral resources are sub-divided, in order of increasing geological confidence, into inferred, indicated, and measured categories. Portions of a deposit that do not have reasonable prospects for eventual economic extraction must not be included in the mineral resource category.

An *inferred mineral resource* is that part of a mineral resource for which tonnage, grade, and mineral content can be estimated with a low level of confidence. It is inferred from geological evidence and assumed but not verified geological and/or grade continuity. It is based on information gathered through appropriate techniques from locations such as outcrops, trenches, pits, workings, and drill holes that is limited or of uncertain quality and/or reliability. An inferred mineral resource has a lower level of confidence than that applying to an indicated mineral resource.

An *indicated mineral resource* is that part of a mineral resource for which tonnage, densities, shape, physical characteristics, grade, and mineral content can be estimated with a reasonable level of confidence. It is based on exploration, sampling, and testing information gathered through appropriate techniques from locations such as outcrops, trenches, pits, workings, and drill holes. The

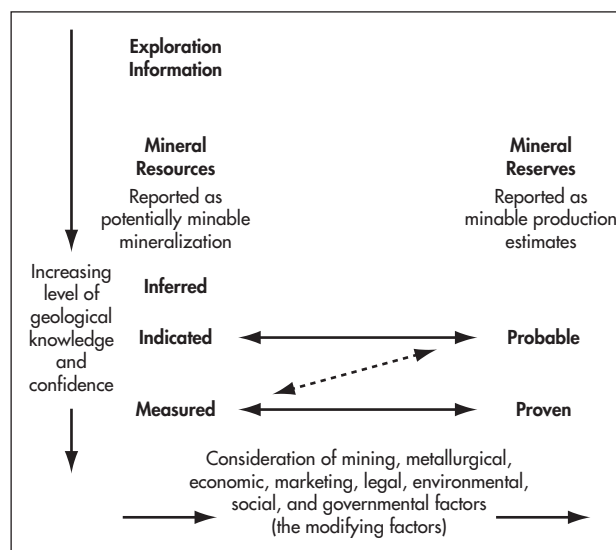

Figure 1. General relationship among exploration information, mineral resources, and mineral reserves

locations are too widely or inappropriately spaced to confirm geological continuity and/or grade continuity but are spaced closely enough for continuity to be assumed. An indicated mineral resource has a lower level of confidence than that applying to a measured mineral resource, but has a higher level of confidence than that applying to an inferred mineral resource.

A *measured mineral resource* is that part of a mineral resource for which tonnage, densities, shape, physical characteristics, grade, and mineral content can be estimated with a high level of confidence. It is based on detailed and reliable exploration, sampling, and testing information gathered through appropriate techniques from locations such as outcrops, trenches, pits, workings, and drill holes. The locations are spaced closely enough to confirm geological and/or grade continuity.

A *mineral reserve* is the economically minable part of a measured or indicated mineral resource. It includes diluting materials and allowances for losses that may occur when the material is mined. Appropriate assessments, which may include feasibility

studies, have been carried out and include consideration of, and modification by, realistically assumed mining, metallurgical, economic, marketing, legal, environmental, social, and governmental factors. These assessments demonstrate, at the time of reporting, that extraction is reasonably justified. Mineral reserves are subdivided in order of increasing confidence into probable mineral reserves and proved mineral reserves.

A *probable mineral reserve* is the economically minable part of an indicated and, in some circumstances, measured mineral resource. It includes diluting materials and allowances for losses that may occur when the material is mined. Appropriate assessments, which may include feasibility studies, have been carried out and include consideration of, and modification by, realistically assumed mining, metallurgical, economic, marketing, legal, environmental, social, and governmental factors. These assessments demonstrate, at the time of reporting, that extraction is reasonably justified. A probable mineral reserve has a lower level of confidence than a proved mineral reserve.

A *proved mineral reserve* is the economically minable part of a measured mineral resource. It includes diluting materials and

allowances for losses that may occur when the material is mined. Appropriate assessments, which may include feasibility studies, have been carried out and include consideration of, and modification by, realistically assumed mining, metallurgical, economic, marketing, legal, environmental, social, and governmental factors. These assessments demonstrate, at the time of reporting, that extraction is reasonably justified.

The U.S. Securities and Exchange Commission (SEC) regulates the reporting of exploration information, resources, and reserves by entities subject to the filing and reporting requirements of the SEC. Decisions as to when and what information should be publicly reported are the sole responsibility of the entity owning the information and are subject to SEC rules and regulations. These rules and regulations vary from time to time and, at any given time, may not be consistent with Figure 1 nor the descriptions of exploration information, resources, and reserves presented here. The advice of securities counsel should be sought in preparing filings for the SEC or other securities regulatory authorities, and in preparing other public disclosures.

* Exact value.

† Conversion factors for land measure may be determined from the following relationships:

1 league = 3 miles (exactly)

1 rod = 16½ feet (exactly)

1 section = 1 square mile (exactly)

1 township = 36 square miles (exactly)

‡ This is sometimes called the moment of inertia of a plane section about a specified axis.
